Morrice, J. J., Taylor, K. M., Blair, J. I., and Young, D. G. (1974). Archives of Disease in Childhood, 49, 898. Preoperative plasma glucose level. The plasma glucose level of 25 infants and children who had routine preparation for anaesthesia and operation has been measured immediately after induction of anaesthesia. The mean plasma glucose level was 66 mg/100 ml. 5 patients had plasma glucose of 40 mg/100 ml or less. In a similar group in respect of age and weight a milk feed was given 4 hours before operation. The mean plasma glucose in the 20 patients in this group was 82 mg/100 ml and no patient had a plasma glucose of less than 60 mg/100 ml. No problems were encountered by giving the milk feed 4 hours before operation.

To minimize the danger of vomiting and inhalation of vomit during induction or on recovery from general anaesthesia it is routine practice to ensure that the patient is presented for anaesthesia after a fast of at least 4 hours. The dangers of vomiting have been stressed so much that in most hospitals patients coming for anaesthesia have been starved for periods considerably in excess of 4 hours. This study was undertaken to determine the blood glucose levels in patients treated in the standard fashion of preoperative fasting and to compare this with a similar group of infants who had been given an oral milk feed 4 hours before operation.

Patients and methods
Patients under 5 years of age who were admitted for relatively minor surgical procedures were studied. They were arbitrarily split into 2 groups. 25 patients (group A) were treated in the routine manner. On investigating the duration of the preoperative period of fasting in these patients it was found to vary from 6 hours to 12 hours and on one occasion was over 12 hours. 20 infants (group B) were prepared in the routine fashion but 4 hours before operation each was given a milk feed of 10 ml/kg up to a maximum of 300 ml. (This upper limit was agreed before starting the series, but none of the patients weighed enough to require this volume.) The basic information on the 2 groups is given in Table I. The mean age of group A was 21·4 months compared with 17·2 months in group B, and the mean weight 10·77 kg and 10·72 kg, respectively. These differences are not statistically significant.

Premedication was given as ordered by the anaesthetist and the patients taken to theatre. Anaesthesia was induced by inhalation of nitrous oxide, oxygen, and halothane. Whenever the patients were anaesthetized a capillary blood sample was taken by a finger or heel prick. All patients had a good peripheral circulation at the time the blood sample was taken. The plasma glucose level was measured using the glucose oxidase autoanalyser method (Morley, Dawson, and Marks, 1968).

Preoperative plasma glucose level

Results

The plasma glucose levels for group A and group B are given in Table I, and the distributions are shown in the Fig. The mean plasma glucose in group A was 66·1 mg/100 ml, and in group B the mean was 82·1 mg/100 ml, a significant difference (P <0·001). In group A 7 patients had a plasma glucose of less than 60 mg/100 ml, while none in group B had a level as low as this. 56% of group A had a glucose level below 70 mg/100 ml compared with 25% in group B. 5 patients in the survey had a plasma glucose level of 40 mg/100 ml or less. We examined whether this was a group of patients who should clinically have been identified as a special category or if they had been fasting for an excessively long period of time (Table II). As far as age, weight, and duration of fasting were concerned, they do not differ from the remainder of the control group.

None of the patients in either group showed overt signs or symptoms of hypoglycaemia. There were no problems related to the induction of anaesthesia in either group nor were untoward signs or symptoms noted in the postanaesthetic phase.

Discussion

The level of glucose in the plasma or blood necessary to maintain normal cellular metabolism in the adult or child is not known with certainty. This has been obvious from the difficulty which there has been in defining the plasma glucose level at which hypoglycaemia exists, and many different levels from 40–70 mg/100 ml have been quoted (Ehrlich, 1971; Pagliara et al., 1973).

In the present survey of patients, group A undergoing standard preoperative fasting before anaesthesia and operation were always found to have a longer preoperative period of starvation than was intended. This was usually 6–8 hours, but in some was longer and on one occasion exceeded 12 hours. The mean plasma glucose for the 25 patients in this group was 66·1 mg/100 ml and 5 of these children were found to have a true plasma glucose of 40 mg/100 ml or less. The low levels occurred in children with a moderate period of starvation and did not simply occur in patients with a very prolonged preoperative fast. That these levels are very low is clear, but what is not clear is whether this hypoglycaemia is of sufficient degree to be potentially dangerous. The patients with these low levels did not show any clinical signs suggestive of hypoglycaemia but it seems undesirable that patients about to be subjected to the added stress of an anaesthetic and operation should come in such a physiological state. During operation there is a rise in the plasma glucose level in the normal adult but it has been shown that children do not respond with a hyperglycaemic reaction to the same degree (Watson, 1972; Clarke, 1970).

A milk feed given 4 hours before operation to a comparable group of children resulted in all patients having a plasma glucose above 60 mg/100 ml. The maintenance of the plasma glucose within these more physiological levels seems desirable at least until more information is available on what the essential glucose levels are for a child about to be subjected to the stress of an operation. Similar results have been reported from a study in Newcastle.

(Bevan and Burn, 1973), and the results of that study are compared with the present study (Table III).

The danger of giving a feed 4 hours before operation is primarily that the patient may retain the milk in the stomach and then vomit either during induction of anaesthesia or in the recovery phase. Inhalation of gastric contents is a known potential danger. In the present series no such problems were encountered and the children who did have a nasogastric tube passed did not have a significant gastric residue. In emergency surgery the accepted practice which evolved through experience has been to accept a 4 hour preoperative fast. In these emergency situations there are often additional factors which will contribute to delay in gastric emptying. In the patient for elective operation it therefore seems desirable that the organization of hospital practice should be revised so that patients do receive a milk feed 4–6 hours before induction of anaesthesia. It is undesirable for infants and children to be starved for periods in excess of this time. Hypoglycaemia then becomes a potential hazard.

We wish to thank the nursing staff and Drs. C. S. Cairns, J. Collins, D. A. Miller, and J. Munro of the Royal Hospital for Sick Children, Glasgow, for help and co-operation in performing this study.
