Spina bifida and maternal Rh blood type

Sir,

Baker and Sherry\(^1\) reported that of 28 mothers of children with spina bifida they found twice as many with Rh-negative blood group than would normally be expected. They stated that they had found no previous reports of such an association. In fact, Wiener\(^2\) strongly propounded the existence of such an association, and McKeown and Record\(^3\) reported a significant excess of spina bifida infants delivered to Rh-negative mothers with antibodies. Other population data (Table 1) are consistent with the hypothesis that a woman who is Rh-negative is at a slightly increased risk of bearing such a child.

Information taken from the 1958 British Perinatal Mortality Survey\(^4\) is shown in Table 2. These data only include stillbirths and neonatal deaths with spina bifida. They show that the excess risk of spina bifida to women who were Rh-negative was apparent only when the woman was of parity 2 or more. This would again be compatible with the theory of an association between spina bifida aperta and maternal rhesus isoimmunisation.

An arteriovenous malformation of the liver giving rise to persistent transitional (fetal) circulation

Sir,

We report the case of an infant with an hepatic arteriovenous malformation who presented with cyanosis and heart failure in whom cardiac catheterisation suggested a persistent transitional (fetal) circulation.

A girl was delivered by forceps at 36 weeks' gestation after a normal pregnancy; birthweight was 2.950 kg. Apgar score at one minute was 6 with a heart rate of 120/min. She failed to establish regular respiration and required ventilation via an endotracheal tube for 12 minutes. She was externally a normal infant without skin blemishes. The placenta was oedematous and weighed 1250 g.

A systolic murmur was noted during resuscitation. She remained cyanosed in 40% \(O_2\) after extubation. At 2 hours she was noted to have a 4 cm enlarged liver with a prominent left lobe. She was in heart failure with a sinus tachycardia of 180/min, a grade 4/6 pansystolic murmur at the lower left sternal border, and prominent peripheral pulses. BP was 75/45 mmHg. A \(Na_2\)-washout with 100% \(O_2\) raised the \(PaO_2\) (descending aorta) to 6-3 kPa (47 mmHg). Chest x-ray showed a large heart with apparently oligoamic lung fields, and an ECG showed biventricular enlargement. An echocardiogram showed all chambers and valves to be normally related.
