SUMMARY Plasma concentrations of gastrin, somatostatin, neurotensin, and enteroglucagon were measured by radioimmunoassay in normal 30- and 45-day-old neonates and age-matched infants with confirmed idiopathic hypertrophic pyloric stenosis. Plasma gastrin and somatostatin concentrations were similar in both groups, whereas neurotensin and enteroglucagon were significantly lower in the pyloric stenosis group.

Since the original anatomical description of hypertrophic pyloric stenosis, this disorder has been recognised as the most common congenital anomaly of the gastrointestinal tract requiring surgical correction. The aetiology of the condition is still unknown. Although various hypotheses have been suggested recent interest has been focused on the gastrointestinal hormone gastrin. It is not however agreed whether plasma gastrin is raised in infant pyloric stenosis.1–4

Apart from gastrin, other gastrointestinal hormones have received little attention. In the present study we have investigated the concentrations of neurotensin, enteroglucagon, somatostatin, as well as gastrin in infants with pyloric stenosis.

Neurotensin is a newly discovered vasoactive peptide,5 which was first found in the synaptosomal and microsomal subcellular fractions of brain tissue, suggesting a role as a central neurotransmitter.6 However, in the distal small intestine, neurotensin is located in specific endocrine cells,7 indicating a possible role as a gut hormone. The development of a radioimmunoassay8 has shown that plasma neurotensin levels rise post-prandially in adults, suggesting a possible role in post-digestive physiology. Although the physiological functions of neurotensin are not fully defined, it has been recently reported that it inhibits gastric motility and gastric acid secretion9 and stimulates bicarbonate output by the pancreas.10

Enteroglucagon is an intestinal hormonal peptide first discovered as a cross-reacting substance in acid alcohol extracts of human small intestines using early radioimmunoassays for pancreatic glucagon.11 Human enteroglucagon has yet to be purified; therefore a study of its physiological actions by exogenous administration has not been undertaken. Some indication of its biological actions comes from the study of a single patient with a renal tumour producing enteroglucagon in high concentrations.12 This patient presented with gross villous hypertrophy and slow intestinal transit time, changes which disappeared after resection of the tumour and after the circulating enteroglucagon concentrations had become normal. Other, indirect evidence also suggests enteroglucagon may have a role as a growth factor of the gut. This includes study of gut hypertrophy in experimental animals (for example, after gut resection and hyperphagia of cold adapted rats, in which an increase in enteroglucagon levels correlated closely with the intestinal crypt cell production rate13).

In man many conditions which tend to cause malabsorption of food are associated with high circulating enteroglucagon and neurotensin. However, both enteroglucagon and neurotensin are low in starvation, where there is gut atrophy.14 Concentrations are also low in cord blood and rise sharply after oral nutrition, although they remain low in infants who are not enterally fed.15

Somatostatin is another peptide that was first discovered in the brain16 and subsequently found to occur in the gastrointestinal tract. Infusion of somatostatin into humans has shown that pharmacologically the peptide possesses powerful inhibitory effects on a number of diverse physiological functions,17 including gastric and pancreatic secretions.

Patients and methods

Twelve term infants, without gastrointestinal disease
Results

Mean plasma enteroglucagon concentrations (Table) in the infants with pyloric stenosis were less than half those of the control infants, at both 30 and 45 days (both P<0.01). These concentrations (both control and pyloric stenosis) by far exceeded the normal adult enteroglucagon concentration (37 ± 5 pmol/l).

The neurotensin concentrations (Table) were, similarly, significantly reduced in the infants with pyloric stenosis, at both 30 and 45 days post-partum (P<0.01 and P<0.05 respectively).

The Figure shows the individual enteroglucagon and neurotensin values in the control and pyloric stenosis infants (values at 30 and 45 days were combined). The mean enteroglucagon and neurotensin concentrations in the pyloric stenosis group were significantly (P<0.001) lower than the corresponding control group.

Plasma gastrin and somatostatin concentrations (combined 30 and 45 days) were not significantly different in the two groups (gastrin, 67 ± 13·5 and 41 ± 7·5 pmol/l, somatostatin 39 ± 7 and 44 ± 5·5 pmol/l, in the infants with pyloric stenosis and controls, respectively).

Discussion

There is very limited information regarding plasma concentrations of gut hormones in infantile pyloric stenosis. One hormone (gastrin) however, has received much attention. Although there are many papers on gastrin levels in infants with pyloric stenosis, these are controversial. Several authors have reported raised gastrin levels whereas others reported no significant differences from control infants. Most authorities now accept that gastrin levels in pyloric stenosis are not significantly different, and the results of the present study confirm this view.

Recently we have investigated plasma levels of several gastrointestinal hormones in infants with pyloric stenosis, including motilin and gastric inhibitory polypeptide. It was found that the upper small intestinal hormones, motilin and gastric inhibitory polypeptide, were significantly lower in the infants with pyloric stenosis. These results, together with the findings of the present study, showing decreased levels of enteroglucagon and neurotensin but similar levels of gastrin and somatostatin, suggest that hormones produced distal to the pyloric sphincter are reduced whereas the proximal hormones are not affected. The reasons for these results are not fully understood. One possible explanation may be the reduced enteral feeding in infants with pyloric stenosis. Thus, because of the pyloric hypertrophy reduced amounts of nutrients reach the intestine which in turn results in under-stimulation of the gut hormone-producing cells. In contrast, endocrine cells in the stomach are stimulated normally.

We have previously described postnatal surges in the basal concentrations of several gut peptides, including neurotensin and enteroglucagon. These increases in hormone levels appeared to be dependent on the presence of nutrients in the alimentary tract. For example, in 6-day-old, preterm babies with hyaline membrane disease, who had been kept on intravenous dextrose since birth, the normal postnatal hormone increase was not seen. These results and those from the present study stress the need for enteral feeding for the maintenance of a normal gut hormone physiology.

The exact physiological functions of enteroglucagon and neurotensin, and indeed the other gut hormones cited above, are not fully defined. Neurotensin and enteroglucagon are thought to play a role in normal gastric motor and secretory function. Enteroglucagon is also thought to exert a trophic influence on the gastrointestinal tract. Alterations in the secretion of these hormones, and also others, may in part explain some of the symptomatology of pyloric stenosis.
