The possible antioxidant role of plasma dl-
α-tocopherol in neonatal disorders such as retino-
pathy of prematurity has received much attention.5
The present findings raise the possibility that de-
ciciencies in the potent human apotransferrin/
ceruloplasmin dependent antioxidant system may be
important in the pathogenesis of retinopathy of
prematurity and similar disorders.
These findings are relevant to the suggestion6 that
increased plasma concentrations of non-haem iron
in the neonatal period are of central importance in
the pathogenesis of retinopathy of prematurity.
Large increases in serum ferritin and transferrin iron
saturation are usually seen in premature infants and
infants born at full term shortly after birth. Addi-
tional sources of exogenous iron in the neonatal
period include dietary iron supplementation and
blood transfusion.6 The present data suggest that
one important effect of increased non-haem iron may
be to neutralise much of the premature infant’s
scarce antioxidant activity, thereby sharply increas-
ing vulnerability to oxygen.

We thank Dr DL Phelps and Dr WA Silverman for their helpful
suggestions. Dr DM Purohit for help in obtaining samples of cord

Simple method for securing umbilical catheters

M SOUTH* AND A MAGNAY†

*Department of Paediatrics, University of Cambridge, and †Birmingham Maternity Hospital

SUMMARY A method for securing umbilical cath-
eters is described. It has been used successfully in
over 350 babies. It is a simple and rapid method
that allows for easy repositioning and, unlike some
established techniques, has no potential for damage
to the preterm baby’s skin.

Since their introduction in the early 1960s the
techniques of umbilical arterial and venous
catheterisation have been accepted into routine
clinical practice. Adequate fixation of catheters is
important: displacement can lead to malposition
of the catheter tip, with consequent poor sampling
and increased risk of vascular thrombosis; catastric-
phic haemorrhage can occur if the catheter ‘falls out.’

Most recommended methods for catheter fixation
involve a combination of tying loops of suture
material around the base of the catheter, and the use
of a ‘goalpost’ bridge of adhesive tape attached to
the catheter and to the skin of the abdominal wall.1

Simple method for securing umbilical catheters

In an attempt to overcome some of these problems we have used a different method of fixation.

Method

When the catheter had been inserted to the required depth, a purse-string 3/0 black silk suture was placed into the cord stump, the needle was left attached to one free end. The base of the catheter was dried with a gauze swab and a piece of 1 cm wide zinc oxide tape (no other tape will do) about 2 cm long was folded around the catheter as close as possible to the cord stump. The needle of the suture was then passed through the tape close to the catheter and tied (fig—left). The needle, with a long thread attached, was then cut off close to the knot. The needle was passed through the cord stump to transfix the umbilical vein, through the zinc oxide tape on the other side of the catheter, and then tied (fig—right). No further fixation was used.

We preferred to place the tip of umbilical arterial catheters at the level of the diaphragm. If assessment by radiography showed the catheter position to be unsatisfactory, it was withdrawn either to the diaphragmatic level (for catheters placed too high) or the low (L3-4) position (for catheters placed too low). To achieve this the zinc oxide tape was cut on either side, close to the base of the catheter, leaving the two free pieces of tape attached by the sutures to the cord stump. The catheter was then withdrawn the measured distance and a fresh piece of zinc oxide tape was folded around the base of the catheter incorporating the two pieces of tape still attached to the stump.

Results

Since February 1985 more than 350 umbilical catheters have been secured using the method described. Three catheters became accidentally dislodged. The babies were over 2 weeks of age and were out of their incubators being weighed at the time. The fixation sutures and zinc oxide tape were all still firmly attached to the catheter, but the dried up cord had separated from the cutaneous stump leaving no secure fixation.

Discussion

This method of catheter fixation was found to be simpler and more rapid to apply than other methods. It does not lead to damage to the skin and allows for easy repositioning. The method is similar to that briefly described by Adams and Rudolph but in our method the tape is stitched to the cord stump and we do not use any form of tape around the infant’s waist.

No records were kept when previous methods were in use, however, the rate of catheter displacement has certainly fallen since the new technique was introduced. Three displacements occurred with catheters that were still in place after the normal time at which the cord separates. Although most catheters are removed before this time, we are attempting to prevent the problem by placing one of the sutures through the cutaneous part of the cord stump.
