The authors previously described Pharmacology and Therapeutics, script. Findings may have some value for do not reflect the true ventricular contours, ventricles and probably that of the brain is the babies of difference between were similar in 37 patients with cystic fibrosis Department of I A CHOONARA, common in concentrations in children. There was no neonatal asymmetry based on the cystic concentration. Plasma concentrations of vitamin K were similar in 37 patients with cystic fibrosis (median 46 ng/l) and 16 controls (49 ng/l). The plasma concentrations were lower than those previously described in adults, but higher than in neonates. There was no association between an increase in prothrombin time and vitamin K$_1$ plasma concentration. Children with cystic fibrosis suffer from malabsorption and are, therefore, prone to deficiencies of fat soluble vitamins. Clinical problems secondary to vitamin K deficiency, however, are rare in cystic fibrosis. Komp and Selden reviewed 59 patients and found only four with an increased prothrombin time and possible vitamin K deficiency. A subsequent study, however, measuring factor II antigen and activity suggested that vitamin K$_1$ deficiency is common in cystic fibrosis.

The measurement of vitamin K$_1$ is technically difficult and there are no data on plasma concentrations in children. We therefore decided to measure plasma concentrations of vitamin K$_1$ in children with cystic fibrosis and also a group of control children.

Plasma vitamin K$_1$ concentrations in cystic fibrosis

I A CHOONARA, M J WINN,* B K PARK,* AND J M LITTLEWOOD

Department of Paediatrics and Child Health, St James’s University Hospital, Leeds and *Department of Pharmacology and Therapeutics, University of Liverpool

Patients and methods

Blood samples (5 ml) were collected from 37 patients (28 fasting) with cystic fibrosis (mean age 10-6 years, range 2–23 years) and 16 children (controls, all non-fasting) who were having venepunctures at the general outpatient’s clinic (mean age 7-6 years, range 3–14 years). The children with cystic fibrosis were attending the Regional Centre at St James’s University Hospital where routine annual assessment included the measurement of plasma concentrations of vitamins A and E, faecal fats, liver function tests, and prothrombin time. Plasma concentrations of vitamin K$_1$ were measured by high performance liquid chromatography coupled to dual cell electrochemical detection. The limit of sensitivity for the assay was 4 ng/l. Statistical analysis was by Spearman’s rank correlation and the Mann-Whitney U Test.

Ethical approval was obtained from the local ethics committee.

Results

The individual plasma concentrations of vitamin K$_1$ are shown in the figure. Nine children (two controls)
Plasma vitamin K₁ concentrations in cystic fibrosis

had plasma vitamin K₁ concentrations below the limit of detection (4 ng/l). There was no difference in the plasma vitamin K₁ concentrations in the non-fasting (mean 71·1, median 45 ng/l) and fasting (mean 76·6, median 48 ng/l) patients with cystic fibrosis. Therefore, the two groups were amalgamated and the results compared with the controls. One of the children in the control group had a very high plasma concentration of vitamin K₁ (2115 ng/l) and was excluded when determining the mean. Although the mean plasma concentration of vitamin K₁ was lower in the patients with cystic fibrosis (75·2 ng/l) than in the controls (172·5 ng/l), the median values were similar (46 and 49 ng/l respectively).

Nine patients had a prothrombin time index of 1·2 or greater and their plasma concentrations of vitamin K₁ are shown in the figure. There was no association between a raised prothrombin time index and plasma concentrations of vitamin K₁ (Mann-Whitney U test, p>0·2).

There was no correlation between the plasma concentration of vitamin K₁ and age, faecal fats, plasma concentrations of vitamins A and E, or the clinical state of the patient (Shwachman and Crispin-Norman scores) (Spearman’s rank correlation, p>0·1).

Discussion

There was considerable interindividual variation in the plasma concentrations of vitamin K₁. There have been no previous studies of plasma concentrations of vitamin K₁ in children outside the neonatal period. The concentrations detected in the control children were lower than that described in healthy adults (mean 260 ng/l, median 210 ng/l, range 100–660 ng/l)³ and higher than that reported in newborn babies (mean 18 ng/l, median 16 ng/l, range 4–45 ng/l).⁶

Although the mean plasma vitamin K₁ concentration in patients was lower than that in controls, the median values were similar. Case reports of undiagnosed patients with cystic fibrosis presenting with bleeding problems describe individuals under the age of six months.¹ Our results suggest that children with cystic fibrosis of the age range studied (no infants) do not have vitamin K₁ deficiency.

The relationship between plasma and hepatic concentrations of vitamin K₁ is unknown. Neonatal hepatic concentrations of vitamin K₁ are significantly lower than in adults. Vitamin K₁ is responsible for the γ carboxylation of clotting factors II, VII, IX, and X and the minimum plasma concentration required for adequate γ carboxylation is unknown. The prothrombin time appears to be an inadequate marker of vitamin K₁ state. There was no association between prothrombin time and plasma concentration of vitamin K₁. The patients with an increase in prothrombin time were slightly older (mean age 12·9 years) than the group in general and it is probable that other factors are involved in causing an increase in prothrombin time.

Routine vitamin K₁ supplementation for patients with cystic fibrosis is not required. Further studies are required to see whether oral supplementation has any effect on those patients with an increase in prothrombin time.

We thank the nursing staff of the Regional Cystic Fibrosis Unit and Mr John Wheeldon for their help in the collection of samples. We also thank Mrs P Hibbett for typing the manuscript.

Water intoxication and hyponatraemic convulsions in neonates

V VANAPRUKS AND K PRAPAITHRAKUL
Department of Paediatrics, Pramongkukalo Medical College, Bangkok, Thailand

SUMMARY We studied two neonates fed diluted formula and excessive water who developed hyponatraemic convulsions; treatment included intravenous hypertonic saline and water restriction. Educating mothers is important to stop recurrences.

From 1967 to 1983 there were 24 cases of infants with water intoxication reported in the literature; their ages ranged from 3 weeks to 11 months.1-4 We report two neonates with seizures secondary to water intoxication.

Case reports

Case 1
A 20 day old girl, the product of a full term, normal delivery, was the first child born to a healthy 20 year old mother. The baby had been well since birth. On the day of admission she was taken to hospital because of irritability and slight abdominal distension not associated with vomiting or diarrhoea. The physical examination was unremarkable and after reassuring the mother the child was sent home. One hour later the baby had a tonic-clonic convulsion and was readmitted to hospital where she was treated with intravenous diazepam. Blood was taken for biochemical and microbiological investigations. The child was given 5% dextrose in one fifth normal saline intravenously.

Physical examination on admission (after intravenous diazepam) showed an unconscious child with a rectal temperature of 36-5°C, pulse rate 120/minute, and respiratory rate 36/minute; there was no anaemia, jaundice, or oedema. The anterior fontanelle was open and soft, the abdomen was slightly distended with normal bowel sounds, and there was no hepatosplenomegaly. The patient responded to deep pain by moving her extremities; her pupils were equal and reactive to light. The white cell count was 5.37 × 109/l with 60% polymorphonuclear cells and 40% lymphocytes, and the haemoglobin concentration was 107 g/l. A microscopic examination of the urine was normal with a specific gravity of 1.005. The blood urea nitrogen was 3.2 mmol/l and the blood glucose concentration 7.8 mmol/l. The concentration of sodium in the serum was 117 mmol/l, potassium 4.8 mmol/l, chloride 92 mmol/l, and carbon dioxide 15 mmol/l. The osmolality of the serum was 240 mmol/kg and of the urine 83 mmol/kg. The cerebrospinal fluid was normal; culture of blood, urine, and cerebrospinal fluid gave negative results.

Because of the severe hyponatraemia in an otherwise healthy infant a detailed history of feeding was taken from the mother. On the day before admission the baby had been given 2 oz of diluted formula consisting of one tablespoon of S26 powdered milk (Wyeth (Ireland) Ltd) in 3 oz of water every four hours; in between each feed the mother gave the infant 4 oz of water. Throughout this period she passed a large quantity of urine. The diagnosis of hyponatraemia caused by excess feeding of water was made and the baby was managed by restricting fluid intake. No further convulsion occurred and the serum electrolytes became normal on the following day.

Case 2
An 8 day old boy, the fifth child of an impoverished family, was born at term after a normal vaginal delivery, weighing 3020 g. The Apgar scores were 9 and 10 at one and five minutes, respectively. The baby had no problem during his nursery stay. At home he was fed 2 oz of a normal dilution of S26...
