Septicaemia and adrenal haemorrhage in congenital asplenia

M P Dyke, R P Martin, P J Berry

Abstract
Five patients developed overwhelming infection as a result of congenital asplenia, which was previously unsuspected in all cases. Each illness followed a fulminant course resulting in death within 24 hours. They illustrate the respective roles of Haemophilus influenzae infection (n=4) and adrenal haemorrhage (n=4) in this condition. We suggest a management protocol for screening infants with abnormalities of the atria or viscera with splenic ultrasound and examination of a blood film for Howell-Jolly bodies. Vaccination and prophylactic antibiotics should be considered for those at risk. Vigorous use of parenteral antibiotics and steroids in suspected infection is recommended.

Congenital asplenia, or polysplenia, may occur in isolation, or as one of several abnormalities of the heart and viscera.1-5 Two main groups of abnormality have been described. Asplenia may be associated with right isomerism, which presents as bilateral trilobed lung and situs inversus of abdominal organs. Polysplenia may occur with left isomerism, bilateral bilobation of the lung, and abdominal heterotaxy.6-7

Over 90% of cases are associated with complex congenital heart disease,2 and the high mortality rate in the early months of life has been largely attributable to this.5 6 8 As surgical techniques and supportive care improve, however, many more children with severe heart disease can be expected to survive the first few months.9 Waldman et al found that infants with asplenia who survived the first month were more likely to die from sepsis than from their heart disease.5 Several reports have described sepsis in asplenic patients and a number of consistent features emerge.8 10-15 Infecting organisms are usually pneumococcus or Haemophilus influenzae. The course of the illness is commonly fulminant with the rapid onset of hypovolaemic shock, disseminated intravascular coagulopathy, and loss of consciousness. Mortality is extremely high, being at least 50% in all series and greater than 80% in many. It is, therefore, becoming increasingly important to seek out evidence of anatomical or functional hyposplenia and to institute measures to protect those infants at risk from overwhelming infection.

We describe five patients who presented to the Bristol Children's Hospital between 1982 and 1990 in whom hyposplenism was not previously suspected and whose illnesses were fulminant and ultimately fatal.

Case reports
CASE 1
A previously well 2 year old boy presented with 24 hours of fever followed by diarrhoea and rigors. Rectal temperature was 40°C and he was centrally cyanosed with tachypnoea, tachycardia, and unrecordable blood pressure. Despite being given antibiotics, plasma, and methyl prednisolone he died eight hours after admission.

Necropsy showed no abnormality except for an extremely small spleen (10 g) and bilateral adrenal haemorrhage. H influenzae type B was cultured from the blood.

CASE 2
A baby girl who was known to have right atrial isomerism, double inlet and double outlet inlet ventricle, a complete atrioventricular septal defect with common atrioventricular valve, and pulmonary stenosis presented at 3 months of age with a simple upper respiratory infection that lasted for 10 days and culminated in acute cardiovascular collapse. She died from cardiac and renal failure within 24 hours of admission to hospital despite full support including peritoneal dialysis.

Necropsy confirmed the cardiac abnormalities and showed that she had no spleen, her stomach and pancreas were on the right, and she had a narrow midline mesenteric root. She also had bilateral adrenal haemorrhages and H influenzae type B was subsequently cultured from her blood.

CASE 3
A 15 month old child presented with a few hours' history of vomiting and fever, followed by loss of consciousness and a single generalised convulsion. There was no localised infection but dextrocardia was noted. Antibiotics and full supportive treatment were started, but the child had a cardiac arrest and resuscitation was unsuccessful. H influenzae type B was cultured from blood and cerebrospinal fluid.

Necropsy showed thoracic and abdominal situs inversus. There were small splenunculi in the right upper quadrant of the abdomen and both adrenal glands were haemorrhagic.

CASE 4
A baby girl was found to have dextrocardia with right atrial isomerism, ambiguous atrioventricular connection, complete atrioventricular septal defect with common atrioventricular valve, double outlet right ventricle, pulmonary valve...
Septicaemia and adrenal haemorrhage in congenital asplenia

Discussion

Although the increased risk of bacterial infection in the asplenic host is well known, congenital asplenia is still largely recognised as a cause of sudden unexpected death in infancy.10-15 Our series illustrates several important features of the problem. Firstly, there is an association with cardiac and other abnormalities. Two of our cases had complex lesions similar to those previously described,1-7 and a third had dextrocardia. Viscera were abnormally placed in three. Secondly, H influenzae type B was subsequently cultured from the blood.

Therapeutic and prophylactic considerations

Death of infection in a congenitally asplenic child is quick, and if it is to be prevented infection must be anticipated. This series focuses attention on the need for a comprehensive programme of screening with preventative and therapeutic measures to reduce the mortality. As the incidence of isolated congenital asplenia is low, screening should be limited to those children presenting with complex heart disease, particularly those with visceral situs inversus, and those with viscera sited abnormally in whom an ultrasonic scan to assess splenic size and a blood film for Howell-Jolly bodies should be done.16 An abnormality of either would be an indication for a 99mTc sulphur colloid scan.17 The use of doxycycline for pneumococcal vaccine in the older patients who have had their spleens removed is now available and should be considered for younger asplenic children.

Antibiotic prophylaxis, traditionally with penicillin for older children without spleens,8-13 should be with amoxycillin to offer protection against Haemophilus spp.8 When amoxycillin resistance in Haemophilus spp is common or in cases of penicillin sensitivity, trimethoprim may be substituted. Perhaps the most important benefit of detection by screening would be the opportunity to institute early treatment with prophylactic antibiotics in cases of suspected sepsis, with steroid supplements to avoid endotoxic and adrenal collapse.
Septicaemia and adrenal haemorrhage in congenital asplenia.
