Intussusception associated with bacterial meningitis

E Crushell, O Flanagan, M Devins, K Dunne, J Gleeson

Abstract
Despite its common association with viral illnesses, intussusception has only rarely been found in the presence of bacterial infections. Two infants are described, both of whom were admitted to hospital with bilious vomiting, drowsiness, and dehydration. Both infants required urgent intravenous volume expansion. Intussusception was confirmed, and reduction was achieved by enema in both cases. Recovery was slow, and one infant developed a seizure. Evidence of meningococcal meningitis was found in both, with septicaemia in one. Neurological outcome is normal to date, and there has been no recurrence of intussusception in either case.

Keywords: intussusception; meningitis; sepsis

The presentation of intussusception in infancy can be misleading as it often mimics that of other diseases such as sepsis, meningitis, and encephalopathy.1 2 Fever and lethargy may be the only symptoms, and differentiation may require ultrasonography and a septic work up. Although intussusception is often found in association with minor viral illnesses,3 the association of bacterial meningitis and intussusception has not been reported previously. Here we describe two cases that presented within one week of each other to two different paediatric units in the West of Ireland.

Case 1
A previously well 5 month old boy was admitted to hospital with a 30 hour history of vomiting. The vomitus was initially undigested food and subsequently became bilious. He developed a petechial rash on the limbs 16 hours before admission. His family doctor, suspecting meningitis, had administered intramuscular penicillin. On arrival he was pale, poorly perfused, and lethargic; his temperature was 38.7°C, blood pressure was 136/78 mm Hg, and heart rate 177 beats/min. He was dehydrated and there were petechiae on the limbs. He was treated with intravenous volume expansion (0.9% saline) and cefotaxime for presumed sepsis. On abdominal examination, there was a mass palpable in the right upper quadrant.

Laboratory tests showed haemoglobin 106 g/l, white blood cell count 19.6 (neutrophils 15.1) × 10⁹/l, and platelets 271 × 10⁹/l. Abdominal radiographs suggested intussusception with a paucity of gas in the right hemi-abdomen. Abdominal ultrasonography showed an ileocolic intussusception with a positive “target sign”. The intussusception was reduced with an air enema. Although the vomiting ceased, there was no real improvement in his clinical condition; therefore it was decided to perform a lumbar puncture. Examination of cerebrospinal fluid (CSF) 48 hours after admission showed a white blood cell count of 992/mm³ (85% polymorphs) in the presence of 8 red blood cells/mm³, protein 0.7 g/l, and glucose 2 mmol/l. No organisms were detected. Blood, urine, and CSF cultures were sterile. Meningococcal DNA was identified in serum by polymerase chain reaction. He was treated with a 10 day course of cefotaxime. Neurological follow up has been normal.

Case 2
A 7 month old girl was brought to hospital with lethargy and vomiting. She had been unwell for one week with intermittent fevers and lethargy. On the morning of admission she had persistent vomiting, initially of undigested food, later becoming bilious. On examination she was sleepy and appeared very unwell, with pallor and mottling of the skin. Capillary refill time was more than six seconds. Temperature was 38°C, and heart rate was 130 beats/min. There was a sausage shaped mass palpable in the right upper abdominal quadrant and the rectum was empty. There were no rashes, but the fontanelle was noted to feel full. The infant was treated with intravenous volume expansion (0.9% saline), and intravenous cefotaxime was begun. Barium enema confirmed an ileocolic intussusception which was reduced hydrostatically. After the procedure, there was little clinical change. She developed a generalised tonic clonic seizure which responded to diazepam.

Laboratory investigations showed haemoglobin 102 g/l, white blood cell count 18.5 (neutrophils 14.6) × 10⁹/l, platelets 641 × 10⁹/l, glucose 9 mmol/l, and electrolytes normal. CSF examination showed white blood cells 16 250/mm³ (95% polymorphs), red blood...
Intussusception and bacterial meningitis

Ireland was eight per 100,000. The probability per 100,000 while the incidence in the West of Ireland was eight per 100,000.

The incidence of meningococcal disease was 14.75 per 1,000 live births. In 1999, the Irish national reported incidence varies from 0.5 to 4 per 100,000.

Obstruction in infancy and early childhood; the incidence of meningococcal disease and vice versa.

A palpable abdominal mass is highly suggestive of intussusception; however it is found in only 63% of cases. In our experience, a sick lethargic infant is usually initially treated with broad spectrum antibiotics until an intussusception is diagnosed and reduced and the infant improves. Spontaneous reduction of an intussusception may occur in a small percentage of cases. However, for the most part, intervention using hydrostatic or pneumatic pressure (and occasionally surgery) is required.

It is notable that in our two patients, despite successful reduction of the intussusception, the overall clinical picture showed no improvement, with persisting poor perfusion and lethargy. Patient 1 had meningococcal meningitis with septicemia (pneumonia and fever) and patient 2 had meningitis, probably meningococcal, without evidence of septicemia.

The relation between intussusception and infection is not clear. Viral infections are commonly associated with intussusception. The seasonal peaks in the incidence of intussusception in spring and autumn coincide with the seasonality of adenovirus infection. Rotavirus has been associated with intussusception, and reports of intussusception following administration of rotavirus vaccine led to its withdrawal in 1999. Although there is a report of intussusception in the presence of aseptic meningitis caused by human herpes virus 6, an association with bacterial meningitis has not been documented previously. Some enteric bacterial pathogens, including Escherichia coli 0157:H7, Yersinia, and Salmonella species, have rarely been implicated in the causation of intussusception.

Local factors are probably the cause of intussusception in the presence of an enteropathogenic organism. It has been postulated that hypertrophied Peyer’s patch is more difficult to find. It may be related to altered gastrointestinal motility as a consequence of circulating inflammatory mediators. This theory is supported by recent animal studies in which intussusception was induced in mice following intraperitoneal injections of bacterial wall lipopolysaccharide.

CONCLUSION

In general, the reduction of an uncomplicated intussusception would be expected to lead to a dramatic improvement in colour and humour. Failure to improve after reduction should prompt a search for coexisting bacterial infections such as meningitis, as found in these cases.

Intussusception associated with bacterial meningitis
