In order to give the best care to patients and families, paediatricians need to integrate the highest quality scientific evidence with clinical expertise and the opinions of the family. Archimedes seeks to assist practising clinicians by providing "evidence based" answers to common questions which are not at the forefront of research but are at the core of practice. They are based on an original format from the Journal of Accident and Emergency Medicine.

A word of warning. These best evidence topic summaries (BETs) are not systematic reviews, though they are as exhaustive as a practising clinician can produce. They make no attempt to statistically aggregate the data, nor search the grey, unpublished literature. What Archimedes offers are practical, best evidence based answers to practical, clinical questions.

Each topic follows the same format. A description of the clinical setting is followed by a structured clinical question. These aid in focusing the mind, assisting searching, and gaining answers. A brief report of the search used follows—this has been performed in a hierarchical way, to search for the best quality evidence to answer the question. A table provides a summary of the evidence and key points of the critical appraisal. For further information on critical appraisal, and the measures of effect (such as number needed to treat, NNT), books by Sackett2 and Moyer3 may help. A commentary is provided to pull the information together, and for accessibility, a box provides the clinical bottom lines.

Readers wishing to submit their own questions—with best evidence answers—are encouraged to read the Instructions for Authors at http://www.archdischild.com.

Three topics are covered in this issue of the journal.

1 Nitric oxide in preterm babies
2 Partial plasma exchange transfusion in polycythaemic neonates
3 Phenytoin in traumatic brain injury

Nitric oxide in preterm babies

Report by Richard Nicholl, Consultant Neonatologist, Northwick Park Hospital

A 25 week gestation male infant, birth weight 520 g, is transferred ex utero to your neonatal unit for intensive care. On day 19 he remains ventilator dependent and is hypoxic on 60–95% oxygen. The oxygenation index (OI; a measure of respiratory failure) is 18. Chest x ray shows clear lung fields. Echocardiography by a senior paediatric cardiologist shows evidence of pulmonary hypertension. In view of these findings it is felt that a pulmonary vasodilator may help. You discuss entering the INNOVO trial (a multicentre...
randomised controlled trial of addition of inhaled nitric oxide (inNO) to babies with severe respiratory failure) with the parents, who agree; the baby is entered into the control (no addition of inNO) arm. In spite of this, parents ask for “everything” (including inNO) to be tried. Reluctantly you agree and inNO is administered as per the trial protocol (you inform the trial coordinators). The baby does not improve, and dies 24 hours later. Was it reasonable to administer inNO to this baby?

Structured clinical question
In ventilated preterm babies with pulmonary hypertension and hypoxia [patient], does addition of inhaled nitric oxide [intervention] reduce mortality [outcome]?

Search strategy and outcome

Commentary
None of the above studies is able to answer our original question. The largest studies were under powered and failed to show important benefits for inNO in preterm babies. The smaller studies showed short term physiological changes; e.g. Subhedar et al: transient fall in OI with 5 ppm inNO; Skimming et al: equal increases in oxygen tension after 15 min of either 5 or 20 ppm inNO.

The possible longer term side effects of inNO are not known. In spite of this, inNO is being routinely used in many UK neonatal units, without the safeguards implicit in participation in a clinical trial (Safeguarding informed parental involvement in clinical research involving newborn babies and infants. A Position Statement. Royal College of Paediatrics and Child Health, December 1999).

(See also Cochrane Library Reviewers’ conclusions—which do not contain the two largest studies above, at time of writing, as they are too recent).

> CLINICAL BOTTOM LINE
- Preterm infants should not be treated with inhaled nitric oxide outside prospective, randomised controlled trials.
- Long term follow up of these babies is needed.

Partial plasma exchange transfusion in polycythaemic neonates

Report by Tammy Rothenberg, Department of Gastroenterology, Great Ormond Street Hospital

You are a neonatal junior doctor looking after the special care nursery. You process a capillary blood sample taken on the morning blood round by someone who has now gone home, and find the haemacrit to be high at 69%. You go back to the baby and find the child to be term, of low birth weight, and admitted to the special care nursery because of low Apgars the previous day. He has not been feeding too well, but the neonatal nurses are not otherwise concerned. He is normal on examination, and his venous haematocrit comes back at 68%. Does this baby need a partial plasma exchange transfusion (PPET)?

Structured clinical question
In an asymptomatic neonate with an incidental finding of raised venous haematocrit [patient], does treatment with a partial plasma exchange transfusion [intervention] reduce adverse neurological outcome [outcome]?

Search strategy and outcome
Using the Cochrane Controlled Trials Register—“Polycythaemia”. Verified using Medline—“polycythamia”, “neonate”, AND “RCT filter”. Six papers identified, of which one irrelevant and one of insufficient quality. See table 2.

Commentary
The research papers all use hyperviscosity rather than polycythemia as the basis for their studies. The test for this is
not routinely available, and so in the clinical setting, polycythaemia is used as a marker for hyperviscosity. Hyperviscosity is the increased internal friction of blood. It varies according to the flow rate; it is in the capillaries, where the flow rate is low, that the hyperviscosity is thought to contribute to reduced tissue perfusion. Red cell concentration (haematocrit) contributes significantly to viscosity; Bada et al found a consistent correlation between the two ($r = 0.5$, $p < 0.001$).

Neonatal polycythaemia is associated with adverse neurological outcome. All papers in the table included a control group of non-polycythaemic or non-hyperviscous infants. The group of infants in the Black et al study showed a significant overall risk of mild developmental delay; this risk was greater than the modest treatment effect, compared with infants controlled for gestational age, birth weight, but not for perinatal risk factors (see table 2A).

The Bada et al study matched the control group for gestational age, birth weight, and perinatal risk factors of fetal distress or asphyxia, pre-eclampsia, and maternal diabetes. Regression analysis was performed to determine the effects of these risk factors on outcome. The risk of adverse neurological outcome was more strongly predicted by perinatal risk factors than the presence of hyperviscosity.

It is notable that there was no abnormal neurology in the infants studied at eight months follow up by van der Elst et al, which may be a result of the type of patients included, the small numbers of patients, or the relatively short follow up period. The subjects of the Black et al study included some who were neurologically normal at 1 year, but had developed signs by 2 years of age. However, the relatively low follow up rate (65% for those alive at 2 years follow up) makes the findings tentative at best. Similarly, although the Goldberg et al study has 80% follow up of the 20 patients, only 6/10 of the observation group were studied, in contrast to 10/10 of the treatment group.

It is important to assess whether these patients are comparable to the clinical scenario. Only the van der Elst patients were selected on clinical grounds (“appearing polycythaemic”), the other patients being selected by a screening process. The other factor that makes the van der Elst patients comparable in particular to this scenario is that the infants included those who had “minor signs”, defined as lethargy, tremulousness, irritability, peripheral cyanosis, vomiting, and poor feeding.

## CLINICAL BOTTOM LINE

- Polycythaemia is a risk factor for later neurological abnormality.
- Partial plasma exchange transfusion has no clear long term benefit in asymptomatic polycythaemia or hyperviscosity, though evidence either way is weak and inconsistent.

Phenytoin in traumatic brain injury

Report by Elizabeth A Hunt, PICU Fellow at Johns Hopkins Hospital in Baltimore

A 12 year old boy is admitted to the paediatric intensive care unit after a motor vehicle collision, where he sustained a severe closed head injury. He lost consciousness at the scene and was intubated in the emergency department for a Glasgow Coma Score of 8 and no gag reflex. The boy has no history of seizure activity in the past or at the scene. Your local “Traumatic Brain Injury Protocol” recommends that he receive phenytoin for seizure prophylaxis. You have recently cared for a child who nearly died from phenytoin hypersensitivity syndrome and would like to know if there is a good indication for the drug.

Structured clinical question

In a child with a traumatic brain injury [patient] does phenytoin prophylaxis [intervention] prevent subsequent seizures and/or improve neurological outcome [outcome]?  

Search strategy and outcome

Secondary sources—none since 1972.

Systematic reviews—two, performed by same authors: Cochrane Library (Issue 3, 2001) and Evidence-Based Medicine (v3, 1998; initially published in J Neurol Neurosurg Psychiatry, 1998); reviewed use of “anti-epileptic drugs”, not just phenytoin.

Primary research—PubMed query using MeSH subject headings: “Cranioencephal Trauma” AND “Epilepsy, Post-Traumatic” AND “phenytoin” and filter “therapy”.

Search results—52 articles; after “therapy” filter: 4 relevant (1 not placebo controlled, blinded or readily available, therefore not included here, but is included in systematic reviews). See table 3.

Commentary

In addition to determining the potential efficacy of phenytoin as prevention for post-traumatic epilepsy, there are other important outcomes to bear in mind. Although anti-epileptics appear to decrease the rate of early seizures, this has not been shown to result in a lower rate of post-traumatic epilepsy, mortality, or improved cognitive outcome. In addition, multiple studies have shown that continued use of phenytoin in this population is associated with “negative effects on cognitive performance”.

One must also consider that phenytoin is not a benign drug. Although studies have not revealed a high rate of side effects...
in patients treated with phenytoin for one week post-injury, physicians must still be aware of the potential for not only serious but potentially fatal reactions to the drug. A search of the literature for adverse reactions to prophylactic phenytoin in head injured patients yielded case reports of intravenous site reactions, exfoliative dermatitis, granulocytopenia, and transient hemiparesis. In other patient populations, phenytoin has been associated with permanent B cell immunodeficiency and fatal phenytoin hypersensitivity syndrome. There have also been multiple publications which show that total phenytoin concentrations can be normal in a trauma patient, yet be associated with high free, unbound concentrations because of low albumin. This may be associated with a higher rate of side effects at normal “therapeutic” concentrations.

Recently, a consensus guideline was published stating that “the routine use of seizure prophylaxis later than 1 week following head injury is not recommended.” The guideline recommends using a risk–benefit analysis to decide whether phenytoin or carbamazepine should be considered for high risk patients in the first week post-injury.

**CLINICAL BOTTOM LINE**

- In the first seven days after serious head injury, phenytoin does prevent seizures in some patients (NNT = 10) but has not been shown to decrease mortality or post-traumatic epilepsy. For high risk patients, a physician must weigh the potential risks and benefits before making a decision.
- If phenytoin is used in trauma patients, measure free, “unbound” phenytoin concentrations to avoid toxicity.
- There is currently no indication for prophylactic phenytoin beyond the first week post head injury.

Towards evidence based medicine for paediatricians
