Arch Dis Child 2002;86:400–402

Aims: To assess the effects of breast feeding habits on sudden infant death syndrome (SIDS).

Methods: The analyses are based on data from the Nordic Epidemiological SIDS Study, a case–control study in which parents of SIDS victims in the Scandinavian countries between 1 September 1992 and 31 August 1995 were invited to participate, each with parents of four matched controls. The odds ratios presented were computed by conditional logistic regression analysis.

Results: After adjustment for smoking during pregnancy, paternal employment, sleeping position, and age of the infant, the adjusted odds ratio (95% CI) was 5.1 (2.3 to 11.2) if the infant was exclusively breast fed for less than four weeks, 3.7 (1.6 to 8.4) for 4–7 weeks, 1.6 (0.7 to 3.6) for 8–11 weeks, and 2.8 (1.2 to 6.8) for 12–15 weeks, with exclusive breast feeding over 16 weeks as the reference. Mixed feeding in the first week post partum did not increase the risk.

Conclusions: The study is supportive of a weak relation between breast feeding and SIDS reduction.

RESULTS

During the study, breast feeding among controls had increased from 56.6% in 1991–92 to 66.1% in 1993 and 73.8% in 1994–95 (any breast feeding at interview). In contrast, there was a decreasing trend among the cases: from 55.7% in 1991–92 to 55.3% in 1993 and 47.4% in 1994–95 (any breast feeding at death). According to Swedish statistics, 49% of infants were exclusively breast fed at 4 months of age, and 19% non-exclusively in 1991. In 1995 the numbers were 62% and 17%, respectively (fig 1).

With exclusive breast feeding over 16 weeks as the reference, the crude odds ratios (95% CI) for exclusive breast feeding were 10.4 (6.0 to 17.8) if the infant was exclusively breast fed for less than four weeks, 8.4 (4.7 to 14.9) for 4–7 weeks, 5.2 (3.0 to 9.3) for 8–11 weeks, and 2.2 (1.2 to 4.0) for 12–15 weeks. When adjusting for smoking during pregnancy, paternal employment, sleeping position, and age of infant, the adjusted odds ratios were 5.1 (2.3 to 11.2) if the infant was exclusively breast fed for less than four weeks, 3.7 (1.6 to 8.4) for 4–7 weeks, 1.6 (0.7 to 3.6) for 8–11 weeks, and 2.8 (1.2 to 6.8) for 12–15 weeks (table 1).

mixed feeding was not a significant risk factor (table 3). No significant interaction with any of the variables mentioned above in the methods section could be found.

When analysing duration of breast feeding, we additionally investigated the influence of AD vitamin supplementation, as we had noticed that an increased risk of SIDS could be found in children not given AD vitamins. However, no significant interactions could be found.

Abbreviations: CI, confidence interval; OR, odds ratio; SIDS, sudden infant death syndrome
DISCUSSION

After a period with a low prevalence of breast feeding in the 1950s and the 1960s, we have seen an increase during the past few decades, and especially in the early 1990s. Breast feeding has been actively promoted for several decades for other reasons than SIDS protection, and was part of the risk reducing campaign in Sweden, but not in Denmark or Norway.

It can be seen from fig 1 that although a large increase in the incidence of SIDS was seen in Sweden between 1975 and 1991, there was no parallel decrease in breast feeding. This is consistent with the findings of Biering-Sørensen and colleagues, who found no rise in the incidence of SIDS accompanying an increase in artificial feeding in Copenhagen between 1956 and 1971. The fall in SIDS incidence after 1991 was caused by abandonment of prone as the preferred sleeping position, in turn promoted by the risk reducing campaigns.

We have estimated the duration of breast feeding, exclusive and non-exclusive, in weeks and used these as measures of breast feeding. This made it possible to look for a dose–response relation, which could represent a biological effect of breast feeding on SIDS risk. Gilbert et al found a tendency for the risk of sudden infant death to increase with the amount of bottle feeding, but this was not significant. Fleming et al found that the effect did not increase with increasing duration of breast feeding, and that the effect disappeared after adjustment for socioeconomic variables. In our study, there was a tendency to a dose–response relation, especially when analysing exclusive breast feeding, but it was not significant. The small influence of breast feeding in the first week is consistent with the well known fact that although SIDS exists it is very rare in the first weeks post partum, and that breast feeding is not yet established at this very early age.

A recent meta-analysis indicated a small but significant effect of breast feeding, with an odds ratio of 2.11 (1.66 to 2.68) for bottle feeding. However, the authors are aware of the possibility that this result may be subject to confounding. In our study, we have taken this into consideration and adjusted for smoking during pregnancy, paternal employment, sleeping position, and age of infant.

Adjustment was made for smoking during pregnancy, paternal employment, sleeping position, and age of infant.
In a previous paper from the Nordic Study,\textsuperscript{16} we have shown that lack of breast feeding (as a dichotomous variable) was a significant risk factor only at the end of the study period. We interpreted this as a sign of the changing importance of risk factors. As mentioned above, breast feeding increased among controls at the same time as it decreased among the cases. This trend was similar in all participating countries, despite the fact that promotion of breast feeding was part of the risk reducing campaign only in Sweden.

One explanation for our results could be that the SIDS cases were recruited from a group of families that was not reached by the promotion of breast feeding. It is plausible that this group was not reached by the risk reducing campaign either, and that the prevalence of known risk factors for SIDS was therefore high. This too, points towards a potentially large influence of confounding. We have tried to account for this, although residual confounding could still be present. However, our study supports the wider picture that breast feeding could be protective against SIDS.\textsuperscript{18}

The mechanism of the protective effect of breast feeding is not clear. One possibility could be that breast fed infants had a lower incidence of infections. In another paper from the Nordic Study, we have shown that the risk of SIDS among breast fed infants was lower than in controls, and that the prevalence of known risk factors for SIDS was therefore high. This too, points towards a potentially large influence of confounding. We have tried to account for this, although residual confounding could still be present. However, our study supports the wider picture that breast feeding could be protective against SIDS.\textsuperscript{18}

ACKNOWLEDGEMENTS

This study was supported by grants from the Swedish Medical Research Council, The Nordic Council, The Medical Society of Göteborg, The First of May Annual Flower Campaign, The Norwegian SIDS Parental Organisation, The Swedish SIDS Parental Organisation, and the Danish SIDS Parental Organisation. The authors thank project coordinator P Schreder and data consultant S Nilssen at the Medical Birth Registry of Norway; M Wennin, Stockholm and J Kjerbeck, Göteborg for special help with data collection; and the regional coordinators.
