Hypoxaemia in children: “abnormal” values may be misleading

Duke et al are to be commended for their interesting report aimed to determine normal oxygen saturation values in healthy infants and children and to assess the performance of clinical signs for predicting hypoxaemia in sick neonates and children with and without acute lower respiratory infections (ALRI). Acute lower respiratory infections (ALRI) account for a substantial burden of disease in children and adults, pneumonia being the leading cause of deaths in children under five, particularly in developing countries. Tachypnoea and chest retraction have been shown to be the most useful clinical signs for determining the presence of pneumonia and thus they are widely used in the diagnosis and management of this condition in children. The World Health Organization pneumonia case detection and management programme, which relies on these simple signs, seems to be justified by the existing body of evidence.

Varying degrees of hypoxaemia may be present in children with pneumonia. However, surprisingly few studies have been performed to assess normal values of haemoglobin oxygen saturation (SpO2) through the use of transcutaneous pulse oximetry, at both sea level and high altitude. Singh’s response to Duke et al rightly emphasises that altitude of studies reported must be taken into account in the interpretation of their results. There are some reports on SpO2 values at mid- and high altitude settings in healthy and sick children. We previously reported normal values of SpO2 in 1264 healthy children living at moderate altitude. This latter finding has obvious implications, as high altitude native children, with higher baseline oxygen saturation levels than newcomers or resident non-native evidence that can be applicable to this setting is a major public health challenge for all of us working in those parts of the world.

Response to Duke et al

We read with interest the article by Duke et al regarding hypoxaemia in acute respiratory and non-respiratory illnesses in infants and children in developing countries published recently in Arch Dis Child. The authors have rightly pointed out the limited availability of published data on the incidence, significance or clinical signs predicting hypoxaemia in infants less than three months of age. With similar concerns we had conducted a study in infants less than two months, a part of which was published in the Archives. We found that tachypnoea, defined as RR > 60/min, predicted hypoxia with 80% sensitivity and 68% specificity. In that study we included six functional and behavioural responses as predictors of hypoxia (table 1). Five of these six variables had a very good sensitivity to detect hypoxaemia.

A very high prevalence of hypoxaemia in the population studied by Duke et al is rather intriguing. Out of total 257 sick neonates and children 52%, were hypoxaemic. Among children with acute lower respiratory infection (ALRI) 73% and those with non-ALRI 32% were hypoxaemic. In an ongoing study we have measured oxygen saturation (by Nellcor® oximeter) in a prospective cohort of 683 children 2–59 months brought to paediatric emergency department (ED) with any respiratory symptom. Oxygen saturation using a fingertip sensor in these children at the time of arrival to ED ranged from 78–99%. The overall prevalence of hypoxaemia defined as SpO2 < 90% was 4.5% (table 2).

An additional 5.1% children had borderline hypoxaemia, i.e. a SpO2 value of 90%. This is similar to a prevalence of 5.9% hypoxaemia defined as SpO2 < 90% in Gambian children, 2–33 months of age, reported by Usen et al. Even in our previous study of 200 infants less than two months, only 38.5% of the sick infants attending ED were hypoxaemic. A systematic review of studies on prevalence and predictors of hypoxia in children by Lozano et al found that the prevalence of hypoxia was dependent upon a number of factors including the setting of the study. The prevalence ranged from 6–9% in outdoor setting to 31–43% in emergency departments to a maximum of 47% in hospitalised children.

Yet, in our study, which represents the situation near sea level (Chandigarh) topographically and the setting of an emergency department, the prevalence of hypoxaemia is much lower than that reported at heights. In light of our data and published literature, we believe that either the definition of hypoxia used by Duke et al is too liberal or the children with respiratory symptoms living at high altitude compensate more frequently to develop hypoxia. More information is needed in this respect to formulate
guidelines for general use. The cumulative data clearly suggest that hypoxaemia is more frequent in children living at high altitude. Interestingly most studies including those of Duke et al on this subject in children 2 to 59 months have been from high altitudes. It is more likely that geographic location, 1600m above sea level is responsible for the high frequency of “hypoxaemia” in their patient population. This, however, may not necessarily be so for oxygen therapy. Hypoxaemia was defined by Duke et al to be applied as a guideline to oxygen therapy almost half of their patients would need oxygen therapy. We need to answer as to whether oxygen therapy makes any difference to outcome of patients labeled as hypoxic. We need to answer as to whether oxygen therapy makes any difference to outcome of patients labeled as hypoxic using cut off limits proposed by Duke et al. It may also be worthwhile to conduct studies with a large sample size at sea level (plains) and in various settings before reaching a conclusion about SpO2 cut off for hypoxia at heights.

Hypoxaemia in developing countries

Drs Huicho, Singi, and Bharti make the important points that definitions of hypoxaemia should be based on altitude-specific normal values and that further research at sea level and higher altitudes is needed. An altitude-specific definition of hypoxaemia (being an arbitrary value of SpO2 more than 2 or 3 standard deviations below the normal population mean) may be different from the threshold SpO2 for giving oxygen. The considerations for giving oxygen are at what level of SpO2 (at different altitudes) oxygen is beneficial, local resource availability, and, in an individual child, confounding factors including the duration of exposure to altitude, age, or co-existent disease such as brain injury, severe anaemia, pulmonary hypertension, and cardiac failure.

We agree with Papua New Guinean neonates and children living at an altitude of 1600m to determine normal range of oxygen saturation. Hypoxaemia in our study was a SpO2 more than 2SD below the mean. In practice our threshold for giving oxygen to sick children (SpO2,<85%: more than 3SD below the mean) was lower than this because of limited oxygen availability. However there is evidence that this is safe and effective. We stated that without further evaluation this should not be applied to hospitals at substantially lower altitudes than 1600m or in areas where oxygen availability is greater.

In comparing the prevalence of hypoxaemia between studies in different health facilities referral and selection biases are likely. Hypoxaemia will be more common in emergency departments of referral hospitals than at primary care settings, and more common still among children requiring hospital admission. The prevalence of hypoxaemia in hospitalised children will depend on thresholds for admission and case-mix. The 491 children in our study constituted about 20% of all the children admitted during the course of the study. A specialist paediatrician, whose practice was to oversee the care of sicker children, enrolled many of the patients, so this was a further source of selection bias. The much lower overall prevalence of hypoxaemia observed by Drs Singhi and Bharti in their emergency department population is therefore understandable. Of note the prevalence of hypoxaemia among sick neonates admitted to Goroka Hospital (43%) was similar to the prevalence among young infants (<2 months of age) attending the emergency department in Chandigarh (38.5%).

It is interesting to consider the effects of altitude on hypoxaemia in children with pneumonia. Some populations living at higher altitudes have a greater tendency to pulmonary hypertension; this susceptibility may be genetically determined and supports Dr Huicho’s statement that ethnic differences in SpO2, at the same altitude are important. At altitude in response to hypoxia, pulmonary blood flow is shunted to the lung apices associated with the redistribution of venous return to the basal lung. This may have an adverse effect on ventilation perfusion matching in the supine position. In addition cardiac expression of natriuretic peptides increases in parallel with pulmonary artery pressure. These and other pathophysiological changes may account for the greater severity and prolonged duration of hypoxaemia seen at higher altitudes.

It is reasonable to evaluate the simple intervention of nursing children with pneumonia and hypoxaemia at high altitude in an inclined head-up position, rather than supine, to determine if this reduces the severity of hypoxaemia. There is a need for more evidence about the prevalence of hypoxaemia at sea level and different altitudes; which children benefit from oxygen; for how long oxygen should be given and the best ways to deliver oxygen in remote settings. Controlled trials of oxygen in mild hypoxaemia may not be justified for ethical reasons, but other evidence will be informative. Before the introduction of pulse oximetry in Goroka we used the World Health Organization guidelines for giving oxygen (cyanosis, inability to feed or severe respiratory distress). With the introduction of pulse oximetry we set a threshold for giving oxygen at SpO2 85%. The severe pneumonia case-fatality rate fell from 10% (26 / 258) pre-pulse oximetry to 5.8% (65/1141) 2 years later. In highland PNG children cyanosis was only detected in 44% of those with arterial saturation 85% below. Although there will be confounders in the before-and-after analysis of outcome, we conclude that clinical signs must miss a significant proportion of children who would otherwise benefit from supplementary oxygen. Further work to determine a protocol for the administration of oxygen based on a threshold SpO2 of 85% (more than 3 SD below the mean for normal children in Goroka) resulted in improved outcomes, and was within available resources.

The costs of oxygen and logistics of transporting cylinders are major problems in many developing countries; Dr Huicho is right that these are important public health challenges. They call for innovative research and development into how best to supply oxygen to children who need it. The role of oxygen concentrators need to be further explored; the combination of concentrators with pulse oximetry would be appropriate technology for many hospitals in developing countries. In countries where the availability of oxygen is crucial to the management of more than 20% of children hospitalised worldwide should be a very high priority; oxygen is one such drug.

Refugee children: don’t replace one form of severe adversity with another

We strongly agree with Fazel and Stein’s view that refugee families require help that is culturally sensitive. Failure to provide appropriate interventions in a culturally sensitive way to these children and their families means we potentially replace one form of severe adversity with another. Contrary to Fazel and Stein’s positive view of school such adversity may include, for some children, integration into the UK educational system. While we agree that psychological trauma can be identified in significant numbers of refugee children, many will have qualities of “resilience” that will have been highly developed by their experiences of war and other adversities prior to their arrival in this country. Having
already contributed so much to their own survival it is inappropriate to perceive refugees simply as victims who require help. Conventional Western responses may be thus inappropriate and ineffective; we need to provide a range of services that are both flexible and innovative. Papadopoulos’ work with Bosnian refugee families is an excellent example of therapeutic innovation. He has referred to “therapeutic presence” and “therapeutic witnessing” as opposed to formal psychotherapy. All of these children have a story to tell although for some the story will be more coherent than for others. In Western psychological terms their plight is somewhat comparable to that of abused children in the care system. Making sense of their experiences in a coherent way is a significant developmental task for them. It is also potentially a shared experience as it is something these children will have in common with others in their family, peers, and wider refugee community. Life story work is an area in which many child mental health professionals, working with abused children, already have considerable experience, and we would like to draw attention to the importance of a developmental approach when working with refugee children. It is a mistake to assume that their developmental parallels that of children growing up in the developed world. Developmental pathways, as well as having occurred in a different cultural context, may have been significantly, and sometimes adversely, influenced by war and refugee experiences.

**Pharmacogenomic can give children safer medicines**

I read with great interest Clarkson and Choonara’s paper on the fatal suspected adverse drug reactions (ADRs) in the UK, and I strongly agree with their conclusions, namely that an evidence based approach to drug treatment is needed to minimise fatalities due to drug toxicity in children. However, recent evidence also suggests that we are now ready for a gene based approach to drug treatment allowing to further minimise the occurrence and the severity of adverse drug reactions. Increasingly complex genetic knowledge can already be used to elucidate mechanisms underlying the adverse events of drugs, while pharmacogenomic work with Bosnian medical evacuees and their families: therapeutic dilemmas. Clinical Child Psychology and Psychiatry 1999;4:107–20.

Ketoacid levels may alter osmotic pressure in diabetic ketoacidosis and precipitate cerebral edema

Inward and Chambers have called for a rethink of the management of diabetic ketoacidosis. In their article they quote a study by Grove L M and colleagues suggesting that pediatricians underestimated the quantum of dehydration in DKA. Overcorrection of dehydration is implicated in precipitating cerebral oedema. On the face of it, it seems implausible that pediatricians who are so adept at estimating body fluid volume and body composition are not osmotically aware, nor were ketone levels studied. However, we did not support the theory that a rapid decrease in extracellular osmolality did not occur. In summary we suggest that changes in ketone body levels be considered, as a factor that can be partially responsible for the cerebral edema often seen during treatment of DKA. We will be glad to share our data at any summit of experts convened to study the enigma of cerebral edema in DKA.

The Lazarus case, Life and Death Issues in Neonatal Intensive Care

When things go badly wrong in the perinatal period there has developed a culture in many “advanced societies” that demands a search for someone to blame. This search for guilt, accountability, punishment, and recompense often results in litigation.

In this thought provoking book John D Lantos describes such lawsuits as “our public morality plays” and uses his experience as a neonatologist, expert witness, and ethicist to create, debate, and crystallise relevant issues of ethics related to the neonatal intensive care of a fictional preterm infant who should have died but did not—The Lazarus Case.

A fictitious neonatologist, Dr Miller, decides to stop resuscitation of a very preterm infant who seems past reasonable care. The baby who might have died survived with severe neurological problems and the parents sue Dr Miller, alleging that stopping treatment was negligent. John Lantos places himself in the role of expert witness and uses questions put by the plaintiff’s lawyers to explore the moral, ethical, legal, and social factors and to illustrate the ambiguities, misunderstandings, responsibilities, and evasions highlighted by the perinatal care of a 25 week gestation infant.

A key question put to Dr Lantos by one lawyer was “Can studying philosophy tell you whether what a doctor does in a particular case is right or wrong?” Probably not is the final conclusion reached by Dr Lantos, but it was just as unlikely that definitive guidance would come from sociology, religious doctrine, strict medical protocols, or any other single source.

There have been many attempts over the past half century to face and explain the moral dilemmas associated with our attempts to save the lives, prevent damage, and encourage optimal development of critically ill preterm infants. The Lazarus Case reviews in a most effective, compelling, erudite, and compassionate way the enormous complexity of these issues. It is highly recommended to all who are concerned with the care of preterm infants and their families and is essential reading for those required to provide medico-legal advice on life and death issues in neonatal intensive care.

Problems in Paediatric Drug Therapy, 4th edn

There is increasing interest in both the clinical and scientific aspects of drug therapy in paediatric patients. This text book by the American Pharmaceutical Association is aimed at the North American market.

It is a reference book aimed at paediatric pharmacists. It covers a wide range of the problems associated with paediatric drug therapy, with chapters on the administration of drugs, fetal toxicity, drugs in breast milk, and both poisoning and drug toxicity, and also specific clinical areas, for example chemotherapy. There did not appear to be any order in the chapters. It would seem more appropriate to put chapter 13 on neonatal doses after chapter 3 on drugs in breast milk than after a chapter on chemotherapy.

There are several chapters with information on the dosage of medicines and it is of interest that these are divided into three separate chapters, one for neonates, one for infants/children and adolescents and one specifically for intravenous drugs. Despite having a chapter specifically on intravenous drugs, the chapters on drug dosing on both neonates and infants/children and adolescents contains details on the doses required for intravenous administration. This makes the book far more difficult to use. The dosage guidance is far less user friendly than publications such as Medicines for Children or the Neonatal Formulary.

It is for this reason I would not therefore recommend Paediatric Pharmacy departments to buy a copy of the book.
