Recent developments in lasers and the treatment of birthmarks

M Waner

Despite rapid advances during the past two decades there are still unanswered questions

There have been numerous advances during the past two decades in the treatment of birthmarks, concerning both efficacy and safety. Although initial results of laser treatment for portwine stains are encouraging, there remain unanswered questions about the long term benefits. The response of other birthmarks to laser therapy is variable, and much work still remains to be done.

PORTWINE STAINS
Laser treatment has become the standard of care for the management of portwine stains. The past two decades have witnessed the progression of these devices from crude, non-selective forms of treatment to highly sophisticated lasers capable of selective photothermolysis. In spite of this, the results of treatment leave much to be desired. Although the vast majority of portwine stains lighten significantly with treatment, only 15–20% clear completely. Moreover, a recent disturbing report revealed what many of us had suspected for some time: portwine stains can recur after treatment. The implications of this are yet to be determined. These findings lead to several important questions: why are we not able to clear more lesions and have there been any recent developments to improve our results?

Vessel depth
Two of the most important considerations are the depth of the vessels and their diameter. For some time, we have known that there is a significant variation in the depth of the vessels in portwine stains. Given the limited depth of penetration of yellow light (1–2 mm at 585 nm), our inability to effectively treat the full thickness of some of the lesions seemed inevitable. Recent work has suggested that there is indeed a correlation between the depth of the vessels and the response to laser treatment. In lesions where the mean depth of the vessels is greater than 1030 μm, the response was poor, whereas lesions with much more superficial vessels (mean vessel depth of less than 830 μm) responded well. In a separate study, the response to treatment also depended on the vessel depth. There are two ways to increase the depth of penetration of light. The first and most obvious is to increase the wavelength of light from the standard 585 nm to 595 nm or even 600 nm. The second is to increase the spot size from 5 mm to 7.5 mm and even 10 mm. Based on Monte Carlo modelling, the larger the spot size (up to 1 cm), the greater the degree of scatter and the deeper the effective treatment depth.

Vessel diameter
The diameter of the vessels also seems to play a critical role in whether or not the lesion will respond to treatment. Dierickx et al showed that pulsedwidths in the millisecond domain would be more appropriate than the standard 500 μs pulse width available on most pulsed dye lasers. This was based on the calculated thermal relaxation times of the vessels that make up these lesions. Therefore, in order to improve our ability to treat larger vessels, the pulse width needed to be increased from 500 μs to the millisecond range.

Surface cooling
The next advance came in the form of surface cooling. Nelson et al showed that cooling the skin surface with a cryogen spray just prior to the delivery of the laser pulse will accomplish two major advantages. Firstly, the likelihood of epidermal damage is reduced; and secondly, the pain of treatment is diminished. A third advantage in the form of greater efficacy soon became evident. Epidermal cooling enabled us to increase the fluence without the risk of epidermal damage. An increase in fluence translates into a more effective treatment and most importantly, a greater effect on the deeper vessels. This important advance led to surface cooling becoming a standard feature of pulsed dye lasers.

Lasers and light sources
Pulsed dye lasers are the most widely used. Since their introduction in the late 1980s, numerous modifications have been made; the most recent features incorporated into these lasers include the following:

• Longer wavelengths (585–600 nm). Most physicians treat in the 585–595 nm range. Anecdotal comments suggest that 600 nm appears to be too long and less effective.
• Bigger spot sizes. Most lasers will offer 7 mm and 10 mm options.
• Longer pulsedwidths. At this time, there are no clinical data to support longer pulsedwidths but anecdotal reports favour a 1500 μs exposure times. Clinical experience with pulsedwidths longer than this has not resulted in improved results.
• Surface cooling. Several techniques of cooling are in use. These include cryogen spray, cold air, a cold window, and a cooled sapphire tip. There appear to be advantages and disadvantages of all of these methods but they do not appear to translate into any difference in efficacy. It is, however, most important that we use one of the methods of cooling.

The features mentioned above do appear to improve our results although at this point, good clinical data has not been published. These developments are however, recent, and it is expected that published clinical data will likely follow.

The most recent generation of pulsed dye lasers with all of the above features as well as a pulsedwidth in the millisecond domain (up to 50 ms) has become available. There are clear theoretical advantages to the longer millisecond pulsedwidth, but whether or not these will translate into better clinical efficacy remains to be seen.

Other devices are also useful. These include KTP lasers and Nd:YAG lasers; more recently a source of non-coherent intense pulsed light has been used with some success.

KTP lasers emit a wavelength of 532 mm (green light) which is as well absorbed by oxyhaemoglobin as light at 585 nm, but unfortunately there is
greater absorption by melanin and more dermal scattering. This will limit the depth of penetration. On the other hand, these devices are capable of millisecond exposure times and can be delivered with surface cooling. It was therefore hoped that they would be useful to treat grade IV (c.f.) lesions. They have in fact been used successfully to treat all grades of portwine stain, but their use is not as widespread as pulsed dye lasers and to date, no published data attests to their efficacy. Nd:YAG lasers have very limited use and are unsafe in inexperienced hands. They can be used to treat cobblestones only.11

Sources of intense pulsed light with appropriate filtering and surface cooling are also useful for treating all grades of portwine stain but once again, their use is not as widespread as pulsed dye lasers.12 In skilled hands, these devices are beneficial.

### PATHOGENESIS AND CLASSIFICATION

Evidence suggests that portwine stains are the result of a segmental, absolute, or relative deficiency in autonomic innervation of the post-capillary venules in the papillary dermis.12-14 This results in a progressive dilatation of the venules of the lesion throughout the life of the patient. An absolute deficiency in autonomic innervation will result in a more rapid progression with early hypertrophy and cobblestone formation. A relative deficiency results in a slower progress of the lesion. Since vessel diameter is such an important factor, a classification based on vessel size would seem logical. Such a classification exists and has both a clinical and a pathological basis. It is helpful in selecting a treatment modality:

- **Grade I lesions**: vessel diameters are in the 80 µm range. These lesions are light pink macules.
- **Grade II lesions**: vessel diameters measure up to 120 µm. These lesions are darker pink macules.
- **Grade III lesions**: vessel diameters measure up to 150 µm. These lesions are red macules.
- **Grade IV lesions**: vessel diameters are greater than 150 µm. These lesions are purple and may become papular.

Since laser treatment destroys ectatic vessels which are the consequence of a deficient autonomic innervation, laser treatment will only impact the effect and not the cause of a portwine stain. It therefore stands to reason that many, if not all, will recur since the autonomic deficiency seems to be segmental and is likely to affect all of the vessels, both large and small, in the affected area.

### A clinical approach

Pulsed dye lasers are the most widely used lasers in this field. Their efficacy with grade IV lesions and lesions with cobblestone formation is poor, probably because of the fact that the vessels that make up these lesions have diameters that require millisecond exposure times. Although the addition of surface cooling and higher fluences may well change this, at this point, KTP lasers and intense pulsed light sources are useful for grade IV lesions.15 In the presence of cobblestone formation, Nd:YAG lasers are useful, but if the cobblestones have been present for several years, surgical excision may be necessary.16 Surgical correction of soft tissue hypertrophy is occasionally helpful, especially with lip and eyelid hypertrophy.17 Surgical excision and full thickness skin grafting is, however, no longer warranted and given the success of laser treatment, this should be strongly discouraged.

### CONGENITAL NEVI

The results of treatment with Q-switched ruby lasers have been disappointing.22 All appear to eventually recur.

A leap into the unknown—working overseas

Like most of these things, the opportunity to work for a year in Brisbane came about by chance, one in a series, in a lifetime filled with lucky circumstances.

I had already decided, with my wife, to take six months of unpaid leave in order to see a bit of the world. More about this another time. The chance to work in Brisbane came up and we rapidly combined it with our travel plans. It is usually hard for doctors working in a March/September system to fit in with doctors working in a January/January system without upsetting someone. Our plans for time out to travel gave us much needed flexibility to reconcile this.

Part of me would have liked to work in the developing world, but for complicated personal reasons this was not possible. So, the question arises: What is the point of working in another developed country? Will the experience be significantly different from staying at home? To try to address this valid point, I set myself some goals and some questions that I wanted to try to answer by the end of my time in Australia. I've had varying success.

Firstly I wanted to get a feel for which of the problems with NHS are the consequence of it being the NHS, and which are common to any health monolith. Clearly I only have an n of 2, but I do have a better feel for what we do because that is what we've always done, and I've seen some of the problems we share with Australia solved in different ways.

Secondly I was keen to experience some branches of paediatrics my region or country couldn't offer me—or could only offer me with greater commitment than I could give in a five year training programme. Thus, I've had short periods of experience in paediatric intensive care, with fixed wing and helicopter retrieval, in oncology, and in rural and (extremely) remote paediatrics. I've also been the Chief Resident, a role which isn't currently found in any hospital in the UK.

And thirdly I wanted to find out more about some of the specific issues I've written about here—the 40 hour week, obesity, teenage smoking, aboriginal health, and so on.

What are the downsides of working overseas?

Well, there are conflicting messages about the amount of time that will be counted towards your CCST when you spend time out of rotation. At various times I was told anything from one to two years of my total two years working overseas. The postgraduate deans are currently under pressure to move SpRs through the system, and so now there is a trend to include more out of programme time. I'd have to be honest and say that the issue didn't really worry me greatly; so I might be a consultant for a year less in the grand scheme of things—where's the hurry? Oddly enough the Royal Australian College of Physicians allows up to six of the total seven training years spent outside Australia. This causes a little anxiety among some senior members, who argue that this isn't really an Australian training at all. There must be some
