Injury

Playground injuries to children
C Norton, J Nixon, J R Sibert

Play value, safety, or both

Play for children has never been more important, particularly as we now know how vital exercise is in promoting health and preventing obesity, both in childhood and also into adult life. Play is also important in establishing social patterns of behaviour that allow children to react to their peers. Public playgrounds form a significant part of the play opportunities for children. It is not surprising therefore that those involved in children’s play have been anxious that playgrounds are as popular and provide as many challenges as possible.

Going along with the drive to make public playgrounds as interesting as possible, there was also a drive to make them as safe as possible. This started with concern regarding playground injuries and deaths in the 1970s, particularly following an analysis in Sheffield led by the late Cynthia Illingworth. This movement led to the introduction of safety features such as impact absorbing surfaces (IAS), changes in equipment entrapment avoidance, height restrictions and guardrails, and changes in materials used in construction of equipment, and design. These changes led to introduction of standards in Britain, Europe (EN 1176 and 1177), and Australia. In the United States, the drive towards safety has been led by the Consumer Product Safety Commission.

It is not surprising however, that the drive for more children’s play, and the drive for more safety have been seen to be in conflict and perhaps incompatible. This debate has been heightened by a recent review by Ball, for the Health and Safety Executive in the UK, suggesting that expensive safety modifications have minimal effect and are not cost effective in terms of reducing injury episodes to children. This article will attempt to answer this dilemma: what evidence is there to suggest that playground safety features work, and are they worthwhile in preventing serious injuries? We also would like to review the research agenda to improve playground safety. Much of the literature on injuries to children in playgrounds has included minor injuries such as abrasions and lacerations; however, the main injuries of concern are limb fracture and head injury. We will pay particular consideration to them.

REVIEW OF THE LITERATURE

We have reviewed the literature on playground injury using the approach of a systematic review. We had a clear search strategy focusing on injuries that actually occurred rather than playground characteristics that might in theory cause injury. The detail of the search strategy is included in the Appendix. Papers that did not include injury data and referred to risk or compliance with regulations were excluded. This literature contains only one intervention study and only one randomised control trial, which is on a method of safety promotion in schools to promote safe playgrounds and not on actual injuries. Our analysis of the evidence therefore has to be largely descriptive.

We identified 37 reports on playground related injury and death. However, some of these were either review articles with no new data or had purely descriptive data. Details of the papers we have relied on are shown in tables 1–5. We have included one interventional study, three correlational studies, and five case control studies.

The majority of the case series identified did not fulfil the criteria for inclusion in our analysis. The studies were generally non-consecutive case series that did not provide information on a range of factors that would influence the predicted profile of injury. However the descriptive detail included within some of these papers provides a valuable historical perspective when considering the impact of modern safety measures. All the papers that provide some evidence are included in tables 1–5: both prior to 1985, when safety surfacing was introduced, and after. We are also including reference to a recent detailed population based analysis of playground injuries.

WHAT INJURIES OCCUR? FRACtURES

Fractures remain among the most common reported fall related injury across the range of reports that date from 1974 to 2001 (tables 1–5). This is despite wide variations in equipment, fall surface, and height of fall. Upper limb fractures are most common; however few studies provide detailed fracture analysis. Ball reports that 71% of fractures were to the upper limb, other studies showed even more fractures of this type. A study by Waltzman and colleagues, looking solely at fall injuries from monkey bars or jungle gyms reported that supracondylar humeral fractures accounted for 40% of upper limb fractures. This high percentage may reflect the equipment type, height of fall, or the age of the child. Information was not available on surfacing, but the authors concluded that surface did not influence injury type.

Proximal fracture appears more common in younger children. The available literature does not inform with regard to the influence of neurodevelopmental status or the interaction between height of fall, type of surface, and fracture type. Lower limb fracture is uncommon.

WHAT INJURIES OCCUR? HEAD INJURY

Severe head injury resulting in skull fracture, intracranial haemorrhage, or neurological disturbance requiring admission to hospital is rare on modern playgrounds. Impact absorbing surfaces were introduced to prevent head injury. Earlier case series before the introduction of these surfaces make clear narrative reference to complex introduction of these surfaces make injury. Earlier case series before the introduction of safety features there may have influenced the fractures between 1974 and 1977 with play-

definitions of the severity of head injury in this paper, but there are written descriptions of injuries. These include “an extensive occipital fracture with loss of consciousness”, “a drowsy girl with a large fracture of the parietal bone”, “two severe skull fractures” and “a serious injury with a fracture of the occiput”.

Rivers and colleagues19 described 40 children admitted to hospital (University College Hospital in London) between 1974 and 1977 with playground related injury. This was a study of hospital admissions however, which may have influenced the fractures recorded. The majority (85%) of injuries resulted from falls and the majority of these (26 of 27 where surface was recorded) were on to concrete, tarmac, or packed earth. Twenty nine of these children had head injuries, of which eight children were unconscious, three had skull fracture, and three had neuro- logical symptoms lasting more than 48 hours.

Oliver and colleagues20 surveyed playground related A&E attendances between 1978 and 1979. This paper contains limited data on 162 injuries. Falls to hard ground were identified as the prime mechanism of injury. Nearly a quarter (24%) of the injuries were skull and limb fractures. Additional information on fracture type was limited to three brief case histories describing two severe skull fractures and a humeral fracture, all requiring hospital admission.

All this suggests that before the introduction of safety features there...
were definite serious head injuries. The definition of concussion or head injury is not clear in many of the series in our review and therefore definite conclusions are difficult to draw. However, it does appear that serious head injuries are rare on modern surfaces.

RISK WITH SURFACES
A number of studies have linked overall injury rates and surface. One correlational study that looked at overall injuries on modern surfaces and tarmac/concrete reported 330 children aged 1–14 injured on public playgrounds. It found that rubber playgrounds had half the risk of bark and a fifth of that of concrete. Chalmers found similar results; the odds of being injured in a fall on a non-impact absorbing surface was 2.28 times that of a fall onto an impact absorbing surface.

INTERVENTION STUDIES
There have been only two intervention studies on playground injuries reported in the literature. An intervention in Cardiff increased bark depth in five playgrounds and replaced monkey bars with a rope climbing frame in one of them. These playgrounds were compared with 14 others, where no changes were made. There were significantly fewer injuries when taken as a whole, and in the playground where the monkey bars were replaced. The reduction in injuries in the four playgrounds where just the bark depth was increased was not significant. This was essentially an opportunistic study; the Council was making changes which were able to be monitored.

The other study was a community intervention trial in New Zealand where 24 schools were randomised to a programme to encourage them to improve playground hazards at schools. The programme was effective.

were definite serious head injuries. The definition of concussion or head injury is not clear in many of the series in our review and therefore definite conclusions are difficult to draw. However, it does appear that serious head injuries are rare on modern surfaces.

RISK WITH SURFACES
A number of studies have linked overall injury rates and surface. One correlational study that looked at overall injuries on modern surfaces and tarmac/concrete reported 330 children aged 1–14 injured on public playgrounds. It found that rubber playgrounds had half the risk of bark and a fifth of that of concrete (p < 0.001). Chalmers found similar results; the odds of being injured in a fall on a non-impact absorbing surface was 2.28 times that of a fall onto an impact absorbing surface. Sosin found that the injury rate on asphalt was six times that on sand.

Therefore, if overall injuries are considered, there are significant differences between impact absorbing surfaces and harder surfaces such as tarmac, concrete, or grass. However, what is the situation with fractures? Macarthur and colleagues, in a case-control study, compared severe (mainly fractures) and minor injuries (mainly facial lacerations). There were no significant differences between the surfaces. Similarly, bark surfaces were not significantly protective of arm fractures relative to concrete in other studies. The conclusion that safety surfaces are ineffective in preventing arm fractures is also confirmed by the lack of improvement in the proportion of fractures in playground injury surveillance with time.

There are biomechanical reasons why safety surfaces may not protect against arm fracture. Experimental models suggest that the current surfaces may be useful in attenuating forces from impacts involving falls from a standing height. However, in higher falls, such as falls from equipment in playgrounds, the surface is not successfully attenuating all of the force components, which result in fracture.

RISK WITH HEIGHT
The relation between height of fall and injury has been confirmed by a number of studies. Macarthur and colleagues found significant difference in height between severe and minor injuries. For fractures, and that the standards in USA, Australia, and Canada might need to be revisited as further data on real injuries from real falls become available (Nixon et al, unpublished data). Chalmers estimated some 10% of attendances at hospital following playground injury were attributable to non-complying surfaces, while 5.6% were attributed to the interaction between the surface and the height of the equipment.
than each piece of climbing equipment in a sample of public parks. Slides were used 4.6 times more than climbing equipment in parks and 1.2 times more in public schools.

**PLAY VALUE VERSUS SAFETY**

Two interests have been identified in educational literature: the need for safety in the playground, and the need to provide a variety of developmental and educational experiences for children. The risk of playground injury is small among preschool children; understandably the main focus for this group is on play experience, and safety advice is directed at supervision and surfaces.39 40 While some level of supervision is expected in schools, playgrounds in public parks cater for a much wider age range among children, and there is little or no supervision. Children’s outdoor play in schools has also been reported to be under threat. Reasons put forward include the following: the time could be better spent on academic pursuits; playground injuries promote litigation; children are at an increased risk of coming in contact with threatening strangers; and teachers and volunteers are less willing to supervise play activities. The value of play to children’s physical and mental development is not challenged; however, it must also be balanced with the child’s right for minimal risk to disabling injury.41 Head injury or serious fractures with lifelong consequences should not be considered part of growing up.

**PLAY MORTALITY**

Although injuries are the leading cause of mortality for children over 1 year of age, all the evidence is that very few children die in playgrounds.42 43 A review of the CHIRPP database (Canada) by Lillis et al during 1990–91 did not identify any fatal playground accidents.44 Chalmers’ study in New Zealand placed the risk at 0.15/100 000 for playground related death.45 In the northern hemisphere Ball and King assumed one death per annum (1985) in the United Kingdom.46 There have been a number of reports47 48 from the United States based on data from the Consumer Product Safety Commission, the most comprehensive being published in 2001.49 From January 1990 to August 2000, CPSC received reports of 147 deaths to children younger than 15 that involved playground equipment (15 per annum). In the 128 incidents for which the location was reported, 90 (70%) occurred in home locations and 38 (30%) in public playgrounds. Over half of these deaths involved unintentional hanging, primarily from ropes, shoestrings, clothing, or homemade swings. A review of the DTI/ LASS (UK) database from 1978 to 2000 did not reveal any deaths coded to playground sites. Although accidents are a leading cause of mortality in childhood, the risk of playground death is small. The predominant cause of death in the current literature is strangulation, rather than head injury due to falls or collision.

**THE WAY FORWARD AND CONCLUSIONS**

Injuries to children in playgrounds is a complex subject. They are many factors that influence them, including the environment of the playground, the behaviour of the child, and frequency of use. This article has focused mainly on environmental factors.

Many of the studies that have investigated playground injuries have described overall injuries. This may have resulted in insufficient focus on the injuries that really matter: those to the head and fractures. A historical review implies that there were serious head injuries before the introduction of modernisation and safety surfacing. Indeed the prevention of head injuries was the reason why safety surfacing was introduced. There are very few head injuries now in modern playgrounds. We therefore believe that safety surfacing is likely to be effective in preventing head injuries and should be continued.

There is also evidence that safety surfacing has prevented overall injuries. However, it does not seem to protect against fractures of the arm. The next step therefore should be to develop surfaces that protect against limb fractures while not compromising safety from head injury.

There are difficulties in implementing intervention studies to prevent playground injuries. There needs to be a cooperative local council (or school). Changes are unlikely to be made just for a scientific study. Despite these difficulties, there are unanswered questions about playground injuries, and further well designed studies will be needed to continue to reduce the risk of injuries in playgrounds. This will require ongoing surveillance.

Although there are still challenges, particularly the prevention of arm fractures, modern playgrounds are safer now than they were 35 years ago. They are still popular with children and mostly provide good play experience for them. They do not need fall heights of over 4 metres, and concrete surfaces to be exciting for children. If they are seen to be safe by parents, they will allow their children to play. This will mean safety for the children and good play experience as well.
