Department of Paediatrics, Hadassah University Hospital, Mount Scopus, Jerusalem

SUMMARY The incidence of necrotising enterocolitis (NEC) in very low birthweight infants (VLBW ≤ 1500 g) was reduced by the delayed onset of enteral feeding. Eight (18%) out of 44 VLBW infants who were in hospital during the first year of the study developed NEC. During the next 12 months 85 similar infants were initially fed by parenteral nutrition only, and then from age 14-21 days with infant formula. During the second year only 3 (3%) patients developed NEC. There were no other relevant changes in management. Throughout the entire study, the onset of NEC in each infant in whom it occurred was after the start of enteral feeding. We recommend avoiding enteral feeding in VLBW infants during the period that they are particularly vulnerable—namely the first 2 or 3 weeks of life.

Necrotising enterocolitis (NEC) is a serious problem in very low birthweight infants (VLBW ≤ 1500 g), and it was therefore of considerable interest when Barlow and colleagues^{1,2} showed that experimental NEC was prevented in a rat by feeding expressed breast milk (EBM). This finding was soon adopted and extrapolated to human newborn infants,³ and neonatal units renewed their interest in human milk banks. New criteria for collecting and using milk were suggested,^{4,5} but after a year of daily struggle to ensure fresh supplies of EBM for our VLBW patients, we were still encountering a considerable number of cases of NEC. A decision to change our feeding policy was made in accordance with the growing evidence for the role of enteral feeding in

the pathogenesis of NEC.⁶⁻⁸ We present our experience during 2 consecutive years of early EBM feeding and delayed formula feeding in VLBW infants.

Subjects and methods

During two consecutive years, from May 1977 to April 1979, 342 newborn infants were in hospital in the newborn intensive care unit of this hospital. One hundred and twenty-nine (37.3%) were VLBW infants (≤ 1500 g). During the second year, the number of admissions and the number of VLBW infants were almost double those of the first year (Table 1).

Table 1 *Characteristics of the infants of very low birthweight (≤ 1500 g) during the 2-year period*

Infants	First year (n = 44)	Second year (n = 85)
Gestational age (weeks)	Range 26-34, mean 28.5 ± 2.0	Range 25-34, mean 27.5 ± 3.0
Birthweight (g)	Range 705-1500, mean 1167 ± 238	Range 620-1500, mean 1046 ± 210
No of referred patients	14 (32)	45 (53)
No of infants		
With Apgar score <6 at one minute	14 (32)	28 (33)
With respiratory distress	32 (72)	64 (75)
Necessitating mechanical ventilation	26 (59)	50 (58)
Undergoing exchange transfusion	18 (41)	31 (36)
Having umbilical artery catheter	40 (91)	76 (89)
Overall survival	29 (66)	58 (68)
Incidence of NEC	8 (18.2)	3 (3.5)*

Percentages are shown in brackets.

* $P < 0.01$, Fisher's exact test.

The feeding policy during the first 12 months was to use EBM exclusively for all VLBW infants. EBM was supplied by the infant's own mother or donated by mothers in the maternity department. The milk was pumped into a sterile glass container, and was used raw or refrigerated within 24 hours. Samples of EBM were sent randomly for culture. The feeding technique was continuous nasogastric or nasojejunal drip, starting on the second or third day of life. The daily increment was 10–20 ml/kg and the total intake was limited to a maximum of 180 ml/kg a day. Most babies were receiving at least half of their intake enterally by the end of the first week. The rest of the fluid intake was given as a 5–10% dextrose infusion.

During the second year the feeding policy was changed. Extremely low birthweight infants (≤ 1000 g) were not fed enterally before age 3 weeks, and those weighing 1001–1500 g at birth were not fed enterally until at least the 14th day, and some not until the 21st day. Feeding consisted of infant formula (SMA, Wyeth Laboratory or Similac, Ross Laboratory) in the same amounts and using the same technique as before. Total parenteral alimentation was used through peripheral veins to provide nutrition until enteral feeding took over. The amount of parenteral fluid was reduced gradually, according to the increase in enteral intake.

NEC was suspected if the characteristic clinical signs were present—namely abdominal distension, gastric residue, bile in the gastric aspirate, and bloody stools. The diagnosis was confirmed either by radiological evidence of pneumatosis intestinalis, free air in the peritoneum or the portal vein, or by pathological examination. Only patients who developed NEC in our unit were considered.

Results

Despite the increase in the number of admissions and the growing number of referred patients during the second year, the incidence of NEC in VLBW infants was reduced from 18.2 to 3.5% ($P < 0.01$) (Table 1).

In VLBW infants who developed NEC, the age at onset of the disease was significantly earlier in the early EBM-fed group ($P < 0.05$) (Table 2). During the entire period no case of NEC was encountered in any patient not fed enterally. The population of VLBW infants was similar in the 2 years for gestational age, birthweight, incidence of birth asphyxia, incidence and severity of respiratory distress, and frequency of umbilical vessel catheterisation (Table 1). Two of the 8 VLBW infants who developed NEC during the first year underwent surgery and 3 of the 8 survived. None of the 3 NEC patients during the second year needed surgical intervention and 2 survived.

Table 2 Infants of very low birthweight (1500 g) who developed necrotising enterocolitis during a 2-year period

Infants	First year (n = 8)	Second year (n = 3)
Gestational age (weeks) range	26–30	26–29
Birthweight (g) range	705–1400	800–1100
No of infants		
With Apgar score <3 at one minute	1	1
With respiratory distress	5	1
Undergoing exchange transfusion	2	2
With umbilical artery catheter	6	2
Age at onset of disease (day) range	7–24	23–60*

* $P < 0.05$ by Fisher's exact test using a threshold.

During the same 2 years, 4 cases of NEC were encountered in patients with birthweight > 1500 g. One of the 4 occurred during the first year, the other 3 during the second. The incidence of NEC in this birthweight group was 1.4 and 2.2% respectively.

Thirty-seven of 43 EBM samples that were cultured grew saprophytic bacteria—such as *Staphylococcus epidermidis* or *Streptococcus viridans*, in concentration of 10^4 or less per 1 ml. No potential pathogenic bacteria were isolated.

Routine cultures of the intravenous alimentation fluids were taken if bacteraemia was suspected. No case of bacteraemia was traced to parenteral alimentation.

Discussion

The incidence of NEC in our nursery was significantly reduced by instituting a policy of delayed feeding in susceptible preterm infants.

Although the exact aetiology of NEC is not yet defined, certain facts concerning its pathogenesis have been elucidated. The absence of the disease in stillbirths suggests it is an acquired condition.⁹ Many now believe that the pathogenesis of NEC depends on the interaction of 3 factors: disturbed intestinal mucosal integrity, the presence of pathogenic bacteria, and availability of a substrate to promote the growth of bacteria—namely food.^{7 10} Injury to the intestinal mucosa may be caused by a wide variety of temporary inevitable events that happen regularly in a newborn intensive care unit—such as asphyxia, shock, umbilical vessel catheterisation, and exchange transfusion.^{7 11 12} Prevention of bacterial overgrowth by the use of prophylactic antibiotics fed enterally has been advocated,¹³ but the hazards of emergence of resistant organisms¹⁴ makes this suggestion potentially dangerous. The only factor that can be controlled satisfactorily is feeding.

Although the two modes of feeding in our nursery were not used simultaneously, the lower incidence of NEC in VLBW infants who received late enteral

feeding is unlikely to be explained by the epidemic cluster of cases, characteristic of some outbreaks.¹⁵ The incidence of NEC in our population of preterm infants with birthweight above 1500 g in whom there was no change in feeding policy, and who continue to receive early enteral feeding with formula or EBM actually increased during the second year.

The role of feeding in our patients is further stressed by the late occurrence of the disease during the second year, and the lack of NEC in all 85 late-fed VLBW infants, during their most vulnerable period—namely the first 2–3 weeks of life.^{7 12 16}

The lack of protection of EBM against the development of NEC in human newborn infants has been reported previously.^{17 18} Trying to explain this failure, Kliegman and colleagues¹⁸ gave 3 possible explanations: contamination of milk by pathogenic bacteria, inappropriate antibody supply due to the use of EBM from women (including the mother) who do not share the infants' intestinal flora, and the effects of storage on the cellular components of EBM. We do not believe that milk contamination could have been a factor in our cases in view of the negative bacteriological findings, but the other 2 explanations may be relevant.

The progress in the use of parenteral nutrition has made it more acceptable for preterm infants, and the danger of bacteraemia has been reduced by using peripheral veins.¹⁹

VLBW infants are at greatest risk of developing NEC and our results suggest that it is safest to withhold enteral feeding in these susceptible infants during the first 2–3 weeks of life.

We thank Professor R Bloch for help with the statistical analysis and Professor S Godfrey for reviewing the manuscript.
