Retroperitoneal teratoma as first sign of Klinefelter's syndrome

Abstract

A 5 month old boy with a retroperitoneal teratoma was found to have a 47 XXY karyotype indicating Klinefelter's syndrome. This observation suggests that patients with the syndrome may be at risk of germinal tumours in sites other than those usually reported (mediastinum, brain, and testes).

(Arch Dis Child 1995; 72: 163–164)

Keywords: Klinefelter's syndrome, teratoma.

Klinefelter's syndrome is a well documented syndrome of sex differentiation in male patients. It is a frequent cause of male hypogonadism with an incidence of one in 600. It is usually characterised by the 47 XXY genotype and typical clinical features,¹ and the diagnosis is usually suspected during adolescence. Reviews of the case reports have suggested that Klinefelter's syndrome predisposes to the occurrence of germinal tumours in particular sites, mostly the mediastinum,² with a relative incidence by site quite different from that known for the germinal tumours diagnosed in subjects without the syndrome.³ We report the first described case of a retroperitoneal teratoma in an infant with Klinefelter's syndrome and hypothesise that the particular distribution of germinal tumour sites in patients with the syndrome could possibly result from a bias in diagnostic search for Klinefelter's syndrome in

patients with tumour sites traditionally considered as typical for this association.

Case report

A 5 month old boy was admitted with a history of crying and constipation of two weeks' duration. The patient was well and the physical examination was normal except for the presence of an abnormal mass in the right upper quadrant of the abdomen.

Ultrasonography showed a large well circumscribed right intra-abdominal mass. The mass exhibited a very heterogeneous echogenicity compatible with the presence of cystic and solid areas, calcified foci, and fat. On nuclear magnetic resonance the dimensions of this retroperitoneal tumour were 11 cm, 9 cm, and 8 cm (fig 1). The tumour was totally removed. Histological examination demonstrated a great variety of tissue components of which neurological elements resembling brain tissue were the most prominent. The tumour also contained skin, hair, and sebaceous glands. Different types of well differentiated epithelia, including pigmented retinal epithelium and gastrointestinal tract tissues could be identified. Islands of cartilage and well organised bone were distributed throughout the tumour. Scanty areas of primitive neuroectodermal elements could be discerned (fig 2). Ependymal-like cells forming rosettes with a small lumen were present. A grade I immature teratoma was diagnosed from the pathology. A chromosome analysis on blood lymphocytes showed a 47 XXY karyotype in all metaphases.

This patient is to our knowledge the first in whom Klinefelter's syndrome has been reported to be associated with a germinal tumour in the retroperitoneal space.

Discussion

Although the incidence of Klinefelter's syndrome is relatively high (1/600), the association of this syndrome with germinal tumours is considered to be more than coincidental, the more so as the distribution of reported germinal tumour sites is very different in patients with Klinefelter's syndrome and in the general population respectively.³ If it were pure coincidence, one would have expected a preponderance of gonadal germinal tumours to have been reported in Klinefelter's syndrome as this site is by far the most frequent within the age range in which the association has been reported so far.⁴

Diagnosis of Klinefelter's syndrome may be difficult. It usually remains unsuspected before puberty and even in adolescence or

Figure 1 Precontrast T1 weighted image on nuclear magnetic resonance showing a large well circumscribed abdominal mass clearly separated from the right kidney, which is displaced inferiorly and medially. Liver compression by the tumour mass is seen. The mass exhibits a heterogeneous intensity pattern with T1 (and T2) signal characteristics indicating the presence of cystic areas, solid components, and fat.

in adulthood it may remain unrecognised. Therefore, the association of a germinal tumour with the syndrome is not always evident and can only be ascertained by a karyotype. This was the case in our patient who was too young to express any clinical signs of Klinefelter's syndrome. Therefore, although the preponderance of mediastinal sites of germinal tumours in patients with the syndrome might be real, it could also be factitious and result from a more frequent search for cytogenetic abnormalities when that particular site is involved. In the first three reports of germinal tumours in patients with Klinefelter's syndrome the tumours were mediastinal.^{2 3 5}

These reports have perhaps biased doctors into thinking that germinal tumours in Klinefelter's syndrome occur exclusively in the mediastinum and might have led to a relative underdiagnosis of the syndrome when

associated with germinal tumours in other sites. An accurate assessment of the incidence and of the clinical features of germinal tumours associated with Klinefelter's syndrome would require a systematic karyotyping of all male patients with such tumours. As in our patient, this would also allow diagnosis of Klinefelter's syndrome at an early age at which usual signs of the syndrome are not yet expressed.
