Metabolic effects of discontinuing growth hormone treatment

F J Cowan, W D Evans, J W Gregory

Abstract

Aims—To evaluate the effects of discontinuing growth hormone (GH) treatment on energy expenditure and body composition, which might help predict those most likely to benefit from early reintroduction of GH treatment in young adult life.

Methods—Body composition was calculated from skinfold thicknesses and dual energy x ray absorptometry (DXA). Resting metabolic rate (RMR) and whole body bone mineral content (BMC) were also measured. Measurements were made before stopping treatment, at discontinuation of GH treatment, and two weeks, six months, and one year later in 11 adolescents with growth hormone deficiency (GHD) and five adolescents without GHD who were treated with GH. Measurements were compared with 10 healthy controls, in whom measurements were repeated one year later.

Results—During the nine months before discontinuation of GH there were no changes in body composition, RMR, or BMC of patients with GHD, nor differences when compared with controls. RMR was reduced by 11.3 kJ/kg fat free mass two weeks after stopping GH in GHD patients and remained suppressed thereafter compared with controls. Percentage body fat increased by 4.3%/year in patients with GHD after discontinuing GH, whereas no changes were noted in control or non-GHD patients at one year. The patients experiencing the greatest reductions in RMR/kg fat free mass at six months showed the largest increases in body fat at one year. No change in BMC was noted in patients one year after stopping treatment.

Conclusion—Important metabolic changes occur early after discontinuing GH treatment. In patients whose growth is complete, these changes might be used to predict those most likely to benefit from continuation of GH treatment into adult life.

(Arch Dis Child 1999;80:517-523)

Keywords: growth hormone deficiency; body composition; resting metabolic rate; bone mineralisation

Growth hormone deficiency (GHD) in adults is associated with increased adiposity,¹ adverse serum lipid profiles,² and reduced exercise capacity.³ Lethargy, low mood and social isolation,⁴ reduced bone mineral density,⁵ and

excess mortality, partly the result of increased cardiovascular deaths,⁶ have also been reported. GH treatment is known to have an anabolic effect in both children and adults, increasing nitrogen retention within days of starting treatment.⁷ Increased nitrogen retention reflects increased protein synthesis and fat free mass, which in turn are associated with increased energy expenditure.⁸ As a consequence of these early metabolic changes, growth hormone (GH) treatment in adults with severe GH deficiency (GHD) produces improvements in exercise capacity,⁹ body composition,^{10 11} and psychological well being,¹² and is now used in the treatment of adults with severe GHD.

At present, it is unclear which individuals diagnosed as having GHD in childhood would benefit from continuing GH treatment into adult life. Currently, GH treatment is discontinued when patients have completed their pubertal growth spurt. Forty per cent of individuals diagnosed as having GHD in childhood no longer demonstrate GHD when re-tested as young adults.¹³ Therefore, it is likely that not all children treated with GH for previously diagnosed GHD in childhood will benefit from treatment in adult life. Important early metabolic changes have been demonstrated after the start of GH treatment in children.⁸ These include an increase in resting metabolic rate (RMR) and fat free mass and a decrease in fat mass. These early metabolic changes are correlated with longer term changes in growth.¹⁴ We hypothesised that reversal of these metabolic effects would occur on discontinuing GH treatment and that the magnitude of these early metabolic changes might be predictive of later changes in body composition. These changes might therefore be used to identify those individuals most likely to suffer adverse effects from discontinuation of GH treatment in early adult life and therefore those most likely to benefit from continuation of treatment.

Subjects and methods

SUBJECTS

Eleven adolescent patients (seven boys) who discontinued GH treatment were studied. The median age was 17.0 (range, 14.5 to 18.5) years and 10 were postpubertal. GH secretory status before treatment with GH had been assessed in these patients by measuring their response to insulin induced hypoglycaemia (nine patients) and glucagon (two patients). GHD was diagnosed when the maximum serum GH concentration was < 20 mU/ml. The median pretreatment maximum GH

concentration was 6.2 (range, 0.2 to 16.9) mU/ml. Seven individuals had isolated GHD and four had multiple pituitary hormone deficiencies. GH deficiency was idiopathic in three cases, associated with a craniopharyngioma in one case, and in seven resulted from treatment for malignancy (astrocytoma, acute lymphoblastic leukaemia (two patients), non-Hodgkin's lymphoma, glioma, rhabdomyosarcoma, and medulloblastoma). There were no differences in the maximum GH concentrations between the individuals with isolated GHD and those with multiple pituitary hormone deficiencies. The median length of GH treatment was 7.5 (range, 1.7 to 11.8) years.

The effects of discontinuing GH treatment in patients with GHD were compared with those obtained in two other groups of adolescents: 10 healthy postpubertal controls (three boys) recruited from a local school, median age 16.8 (range, 16.5 to 17.1) years and five individuals (one male) who had been treated with GH but who were did not have GHD, median age 16.2 (range 14.4 to 17.4) years. Three of these had Turner's syndrome, one Leri-Weill syndrome, and one normal variant short stature (maximum serum GH concentration, 53.2 mU/ml during serial measurements made every 20 minutes overnight). Patients with Turner's syndrome and Leri-Weill syndrome did not undergo pretreatment GH testing but there were no clinical signs to suggest GHD and a cause for their short stature was evident. The median length of GH treatment was 3.2 (range, 2.0 to 7.0) years. Four patients were postpubertal. The three girls with Turner's syndrome all had ovarian failure and were being treated with a combination of ethinyloestradiol and norethisterone (Loestrin 20). These non-GHD patients were included to

assess the effect of stopping GH per se, to determine whether any metabolic changes seen in the patients with GHD were indicative of continuing endocrinopathy and not simply a result of discontinuing GH treatment.

METHODS

In patients treated with GH, measurements of RMR and body composition were made at a median of 9.4 (range 4 to 20) months before discontinuing GH, at discontinuation of GH, and two weeks, six months, and one year later. Similar measurements were made on two occasions a year apart in the healthy controls. Height was measured using a wall mounted Harpenden stadiometer (Holtain Ltd, Crymch, Dyfed, UK) and weight by a beam balance (Avery Ltd, Birmingham, UK). Body mass index was calculated from weight (kg)/height (m)². Measurements were expressed as standard deviation scores (SDS) using the 1990 growth standards for British children.^{15 16} Puberty was assessed by the method of Tanner.¹⁷

Resting metabolic rate

At each visit, RMR measurements were made under standard conditions, early in the morning in the fasted state, with the subjects resting supine in a thermoneutral environment. On each occasion, the first 10 minutes of the RMR measurements were discarded to ensure that steady state resting values were obtained. Oxygen consumption and carbon dioxide production were measured by ventilated hood indirect calorimetry (Deltatrac II MBM-200 metabolic monitor; Datex, Helsinki, Finland) and RMR was calculated using the equation of Weir.¹⁸ Because RMR is dependent on body size and the proportion of metabolically active tissue, RMR (kJ/day) has also been expressed adjusted for body size (kJ/kg body weight/day) and for fat free mass (kJ/kg fat free mass/day).

Body composition

Body composition was measured by skinfold thickness and dual energy x ray absorptometry (DXA). Skinfold thickness measurements were made using a Holtain skinfold caliper at the triceps, biceps, subscapular, and suprailiac

sites. Body density was calculated from the sum of the skinfold measurements using the sex specific equations of Durnin and Rahaman.¹⁹ The proportion of body weight accounted for by fat was calculated using the equation of Siri,²⁰ from which the weight of fat free mass and fat mass could be derived for each individual.

DXA measurements of fat free mass, fat mass, and percentage fat were performed using a QDR 1000/W scanner (Hologic Inc, Waltham, Massachusetts, USA).²¹ DXA measurements of body composition in the healthy control individuals were only made at the initial assessment, although skinfold thickness and RMR measurements were repeated one year later.

Bone mineralisation

Whole body bone mineral content (BMC) and bone area (BA) were measured by DXA scanning using the QDR 1000/W scanner. Conventionally, bone mineral data derived from DXA have been presented as areal density, yet this fails to account for changes in BMC that result from changes in age and body size. Therefore, predictive formulae were used for BMC that provide a method for interpreting the measured BMC, which is independent of these variables.²² The measured BMC was expressed as a percentage of the predicted value (%BMC), which allows comparison of values in subjects with a wide range of body size and age.

Our study was approved by the South Glamorgan and Newcastle local research ethics committees and informed consent was obtained from each patient.

STATISTICAL ANALYSIS

Group means were compared using independent t tests. Changes within subjects were compared using paired t tests. The different diagnostic groups were compared using one way analysis of variance (ANOVA). Where the F ratio was significant ($p < 0.05$), Tukey's post

hoc multiple comparison test was applied. Agreement between the two methods of measuring body composition was assessed by the method described by Bland and Altman.²³

Results

Patients with and without GHD and healthy controls were of similar age (table 1). The GHD and non-GHD patients were shorter and lighter than the controls, with the non-GHD patients being significantly shorter than those with GHD (table 1). There were no differences in body mass indices between the groups. The non-GHD group had received GH for a shorter median time than those with GHD but the difference was not significant.

RESTING METABOLIC RATE

While on GH treatment there were no significant differences between RMR values for patients with GHD compared with the healthy control subjects, whereas the non-GHD group had a significantly higher RMR at discontinuation of GH treatment. There were no significant changes in RMR in the GHD group or the non-GHD group during the year before discontinuation of GH. Significant reductions in RMR/kg fat free mass/day were seen two weeks, six months, and one year after discontinuation of GH treatment (11.3, 12.6, and 11.8 kJ/kg fat free mass/day, respectively; $p < 0.01$) only in those with GHD. In the non-GHD group, RMR/kg fat free mass/day remained significantly higher than in the GHD group on each occasion, and no significant reduction was noted over the year of the study. After one year, the healthy control subjects had a significantly increased RMR when expressed as kJ/day, but not when corrected for body size and composition (table 2). RMR/kg fat free mass/day was significantly lower in the patients with GHD compared with controls and non-GHD individuals one year after stopping treatment. Although RMR/kg fat free mass/day was higher in the non-GHD group while on GH than in controls, there was no difference between the two groups one year after discontinuing GH (fig 1).

BODY COMPOSITION

Percentage fat values were consistently higher when measured by skinfold thickness than by DXA. There was a mean bias of 4.4% (limits of

agreement, 11.5% to -2.7 %) when skinfold thicknesses were compared with DXA measurements (fig 2).

When measured by skinfold thicknesses, patients with GHD had an increase in fat mass and percentage body fat at six months (2.3 kg and 3.0%, respectively; p < 0.05) and one year (3.9 kg and 4.3%, respectively; p < 0.05) after stopping GH (table 3; fig 3). DXA measurements revealed even larger changes (6.4 kg and 5.9%, respectively, at six months and 6.5 kg and 7.8%, respectively, at one year; all values p < 0.05) in the patients with GHD (table 4). Over the year, healthy control subjects also demonstrated a small mean increase in fat mass (1.8 kg) measured by skinfold thicknesses (p < 0.05), although this change was not

significant when expressed as percentage body fat. No significant changes in fat mass were demonstrated in the non-GHD patients. Percentage body fat was increased in the non-GHD group at six months, when measured by skinfold thickness (4.1%; p < 0.05) but not when measured by DXA, and at a year was no longer significantly different from the time when GH was discontinued. No significant changes in fat free mass were seen in the healthy control group or either of the patient groups.

There were significant associations between changes in RMR/kg fat free mass/day and subsequent changes in body composition in the GHD group, with those individuals having the largest reductions in RMR/kg fat free mass/day at six months having the largest increases in fat mass (fig 4) and percentage fat (fig 5) at a year (p < 0.05). No such association was seen in the

Figure 3 Mean (SD) percentage fat by skinfold thickness before discontinuing GH treatment (Pre-dis), at discontinuation (At dis), and two weeks, six months, and one year after stopping treatment. *p < 0.05, compared with values at discontinuation of GH treatment; [†]p < 0.05 compared with controls at one year.

Figure 4 Change in resting metabolic rate (RMR)/kg fat free mass at six months after stopping treatment and subsequent change in fat mass at one year in patients with growth hormone deficiency.

Figure 5 Change in resting metabolic rate (RMR)/kg fat free mass at six months after stopping treatment and subsequent change in percentage fat at one year in patients with growth hormone deficiency.

non-GHD group. The changes in RMR/kg fat free mass and the subsequent changes in body composition were similar whether the patients with GHD had isolated GHD or multiple pituitary hormone deficiencies.

There were no significant relations between pretreatment GH concentrations on stimulation testing and the metabolic changes that followed discontinuation of GH treatment.

BONE MINERALISATION

There were no significant differences in %BMC when the patients with GHD were compared with the controls (mean (SD), 97.5% (3.9%) and 101.0% (5.8%), respectively) at the time of stopping treatment. However, the non-GHD group had a lower %BMC (mean (SD) 94.7% (3.4%)) than the controls ($p < 0.05$). No significant changes in BMC were noted over the year of the study in either GHD group or the non-GHD group.

Discussion

Our study has shown that RMR is reduced two weeks after stopping GH treatment at the end of the pubertal growth spurt and remains suppressed up to one year later in individuals previously identified as having childhood onset GHD when compared with healthy controls. An increase in fat mass and percentage body fat are evident six months after stopping GH and these body composition changes remain one year after discontinuing treatment, although no further significant increases occur between six months and a year. This mirrors the effects seen after starting GH treatment in children, when maximum changes in fat free mass occurred in the first six weeks, with only small increases thereafter.¹⁴ However, an initial increase in RMR/kg fat free mass/day values in newly treated patients after six weeks of GH treatment had returned to pretreatment levels by 12 weeks,¹⁴ whereas in our study, RMR values remained suppressed one year after discontinuing treatment.

It is interesting to note that while on GH treatment, non-GHD patients had a higher RMR/kg fat free mass/day than the healthy controls, but a year after discontinuing therapy, values were similar. This might suggest that the non-GHD patients experienced an abnormally raised RMR while receiving GH treatment, perhaps as a consequence of abnormally raised

serum GH concentrations. Whether this might have potentially adverse effects on future health is unknown.

We have shown important early metabolic changes on discontinuing GH treatment and subsequent changes in body composition. Changes in fat mass were only seen in the patients with GHD. Although percentage fat was increased in both GHD and non-GHD groups, when measured by skinfold thickness at six months, this was only sustained in the patients with GHD at one year. The control group also demonstrated an increase in fat mass at one year, although this increase was not as large as that seen in the GHD group, and no change in percentage fat was noted. The control group contained a higher proportion of girls than the GHD and non-GHD patient groups. We recruited the controls from a local school and were limited by the smaller number of boys who agreed to take part. It might be expected that the healthy control girls would experience larger increases in body fat during adolescence than boys and thus the observed difference between the patients and controls over the year after GH treatment is of even greater clinical importance. The changes in body composition seen in patients with GHD previously treated with GH cannot be attributed entirely to the metabolic sequelae of stopping the GH treatment, but may partially reflect the normal changes seen at the end of puberty. Clearly, influences other than GH affect body composition in these individuals. Our study did not attempt to assess changes in physical activity or dietary intake, either of which might affect body composition. It is interesting to note, however, that no significant changes in body composition were seen in the period of the study during which the patients remained on GH treatment (median, 9.4 months). Four patients had multiple pituitary hormone deficiencies and were on replacement treatment with other hormones (such as thyroxine, sex steroids, or hydrocortisone), which might have implications for body composition. The serum concentrations of these hormones were monitored before and during our study and remained within the relevant therapeutic ranges, suggesting that these concurrent treatments were unlikely to have influenced the results.

Whole body BMC was not significantly reduced in the patients with GHD nor were significant reductions noted one year after discontinuing GH treatment. This is in keeping with some studies in young adults,²⁴ although others have demonstrated considerable reductions in bone mineral density in older individuals with prolonged GHD.⁵ Our findings suggest that adequate GH treatment in children prevents the development of relative osteopenia, which may be seen in adults who have experienced prolonged GHD. Longer follow up may be necessary to detect reductions in bone mineralisation after stopping GH treatment. Reduced BMC was demonstrated in the five non-GHD patients. Three of these had Turner's syndrome and the reduced BMC may reflect suboptimal oestrogen treatment. One

other had Leri-Weill syndrome and the abnormal bone development in this syndrome might be expected to affect BMC measurements.

Presently, adolescent patients discontinue GH treatment when they have completed their growth. Because GH is now available for the treatment of GHD in adult life, there is increased interest in identifying those individuals diagnosed as having GHD in childhood who would most likely benefit from longer term treatment into adult life, once growth has been completed. At present, the licence for GH treatment in adult life permits treatment in adults with profound GHD (< 5 mU/ml), although previous studies of the metabolic effects of GH treatment in adult life have shown benefits in populations with pretreatment GH concentrations varying between 3 mU/ml and 10 mU/ml.²⁵⁻²⁷ It is unlikely, therefore, that an absolute concentration of GH could be used to determine which individuals would benefit from GH treatment in adult life. Given the limited correlation between biochemical measures of GH deficiency and some of the subsequent physiological effects (such as growth) of treatment, and also the poor correlation between the results of GH testing in earlier childhood with results obtained in young adult life,¹³ our results suggest that the decision for continued treatment of GHD into adult life should be based partly on evidence of physiological benefit rather than purely on the results of GH stimulation testing performed in early childhood. It is currently recommended that re-evaluation of the GH response to pituitary stimulation testing should also be included in the assessment of the need for longer term GH treatment. Unfortunately, such data are not available for most of our patients, many of whom declined further testing of GH secretory status at this stage.

Other studies have investigated the effect of discontinuing GH treatment. Increases in fat mass have been demonstrated by bioelectrical impedance measurements in individuals with continuing severe GHD, when measured three months after discontinuing GH, whereas no change was noted in patients without GHD.²⁸ Percentage body fat measured by DXA scanning has also been shown to be increased at six and 12 months after discontinuing GH but in this particular study the control group showed no such increases.²⁹ Small and variable reductions in muscle strength and size have been shown to occur one year after discontinuing GH treatment in a small group of adolescents, but changes in the normal population at this age are not well documented, making it difficult to interpret this finding.³⁰

However, to our knowledge, our study is the first to demonstrate that abnormalities of RMR can be measured within a short time interval of discontinuing GH treatment. One of the aims of our study was to evaluate whether the early metabolic effects of discontinuing GH might be predictive of longer term adverse effects on body composition and whether these effects could be used to identify those individuals most likely to benefit from treatment with GH

in early adult life. We have demonstrated that those individuals experiencing the greatest reduction in RMR/kg fat free mass subsequently show the largest increases in body fat, although the reduction in RMR does not explain all of the changes in body fat ($R^2 = 0.49$; fig 4), given that some increase in body fat may be expected in normal healthy adolescents of this age. We would suggest that measuring early changes in RMR on discontinuing GH treatment could be used to identify those individuals who would benefit from continuation of GH treatment into adult life. In units where the necessary equipment is unavailable, measurement of skinfold thicknesses to determine changes in body composition during the year after stopping GH could be used to identify those individuals with large increases in body fat who should be encouraged to undergo repeat assessment of GH secretory reserve. GH treatment may then be reintroduced at an early stage in those with confirmed GHD to prevent further adverse effects on body composition.

We are grateful to Mr JH Pearce, Mr D Coleman, and Mrs RJ Pettit for assistance with the DXA measurements; Professor A Aynsley-Green and Dr PJ Smith for advice on study design and for allowing us to study their patients; and Pharmacia-Upjohn for financial support for the study.
