Acute and late coronary outcomes in 1073 patients with Kawasaki disease with and without intravenous γ-immunoglobulin therapy

Ming-Tai Lin,1 Li-Chuan Sun,2 En-Ting Wu,1 Jou-Kou Wang,1 Hung-Chi Lue,1 Mei-Hwan Wu1

ABSTRACT
Objective To explore acute and late coronary outcomes and their risk/modifiers in patients with Kawasaki disease (KD).

Design Retrospective study.

Setting and patients 1073 patients with KD identified from a tertiary care medical centre (1980–2012; 8677 patient-years).

Main outcome measures The acute coronary severities and late outcomes (survival free of coronary aneurysm persistence and ischaemia) were assessed.

Results Coronary arterial lesions occurred in 40.6% of cases at their acute febrile stages, and persisted beyond 1 month in 196 (18.3%, M:F=138/58) patients: 125 (11.6%) had small aneurysms, 44 (4.1%) had medium aneurysms, and 27 (2.5%) had giant aneurysms. At follow-up (1–46 years), coronary aneurysms persisted in all with giant aneurysms, in 55% of those with medium aneurysms (18% with stenosis), and in 9% of those with small aneurysms. Ischaemia events occurred in 14 patients (M:F=13/1) and caused four deaths. Among the patients with KD with coronary aneurysms, 10-year ischaemia event-free and aneurysm persistence probability was 87.5% and 20.6%, respectively. The only independent risk for aneurysm persistence was the aneurysm severity 1 month after KD onset ($\chi^2=80.73, p<10^{-3}$). Male patients and intravenous γ-immunoglobulin (IVIG) therapy were independent risk factors of initial coronary severity but were not associated with the late coronary outcomes, even in severity stratified subgroups.

Conclusions The coronary severity 1 month after KD onset is most crucial to the late coronary outcomes. Although IVIG use improves the initial severity of coronary lesions, it does not further modify the long-term fate of coronary aneurysms.

INTRODUCTION
Since the first report in 1967 from Japan, Kawasaki disease (KD) has become the most common form of paediatric systemic vasculitis.1 Despite receiving intravenous immunoglobulin (IVIG) therapy, coronary arterial lesions (CALs) occurred in 5–20% of patients with KD during the acute stage.2–4 CAL may persist and even progress to stenosis or obstruction. Therefore, CAL following KD is now the leading cause of acquired heart disease in children.3–7 In our previous study focusing on the period before the introduction of IVIG therapy, CAL occurred in 44% of patients.8 Among them, most of the dilation regressed and all giant aneurysms persisted. IVIG therapy became available in 1986, but only became standard treatment after the implementation of Taiwan’s National Health Insurance programme in mid-1995, which covers the expense.7,9 The relationships between late KD coronary outcomes and the risk/modifiers, like gender and IVIG use, have never been studied as yet. We therefore conducted a longitudinal study based on patient enrolment since 1980 to delineate this issue.

METHODS
The study was approved by our Institutional Research Board.

Study population
The diagnosis of KD in this study was made based on clinical criteria for KD.10 All children received echocardiography during the febrile stage and the subacute phase (1, 3, 6 weeks, and 3 months after fever onset, and the subsequent frequency varied depending on the severity of the CAL), except patients diagnosed before 1984. CALs were defined as previous studies.4,11 However, only cases where CAL persisted for more than a month after disease onset were considered as coronary aneurysms.
Based on the aneurysm size, the severity of coronary aneurysms was classified as small (≤4 mm), medium (4–8 mm) and giant (>8 mm). CALs and the regression were diagnosed based on two-dimensional (2D) echocardiography and confirmed using CT or angiography if indicated (when 2D echocardiograms showed regression of coronary aneurysms that had been greater than 4 mm, or for the patients who exhibited symptoms of myocardial ischaemia, or for a regular follow-up of giant aneurysms every 3–5 years, figure 1). For patients with echocardiography follow-up, regression was defined when echocardiography demonstrated coronary arteries with normal appearance and size, as well as normal cardiac function. Low-dose aspirin was given for at least 6–8 weeks and until when echocardiography confirmed the regression of coronary lesions. ECG was performed annually and whenever patients reported chest tightness. Diagnosis of myocardial ischaemia was made based on ST segment changes and/or stress radionuclear imaging results (figure 1).

Statistical methods
We performed analyses using SPSS V.11.5. Data were expressed as mean±SD (medians with ranges), and we used Mann-Whitney test for two-group comparisons. The χ² test was used to compare categorical data. For the time-related events and outcome variables, like persistence of coronary aneurysm, we used Kaplan-Meier estimates to draw event-free curves and tested their associations with candidate-independent factors by using log-rank tests. To estimate regression probability, the follow-up period ended when the CAL regressed or patients did not attend the scheduled follow-ups. Variables related to time-related events with p<0.1 in the univariable analysis were entered into the multivariate model. Statistical significance was set at p<0.05.

RESULTS
Patient characteristics and coronary severity 1 month after KD onset
Between 1980 and 2012, 1073 patients were diagnosed with KD (M/F ratio=664/409, 1.62), including 22 with atypical KD with CAL. The age at diagnosis ranged from 1 month to 18 years (median 1.59 years). The proportions of patients with infarct onset (28% vs 34%, p=0.09) and male (61% vs 63%, p=0.46) in patients without and with IVIG were not statistically different. IVIG therapy was not administered in 366 patients (34.1%). Our national health insurance was implemented in
mid-1995 and reimbursed the IVIG only when fever persisted for more than 5 days and (1) more than four presentations of diagnostic criteria were fully filled or (2) there were less than four characteristic criteria but positive coronary involvement. Hence, to avoid the potential selection bias due to the diagnostic era, we stratified our cohort into two strata: early group (1980–1995) and late group (1996–2012). IVIG was given in 34.6% (112/324) and 79.4% (594/748) of the early and late group of patients with KD, respectively (χ²=200.2, p<10⁻⁴, figure 1). None received corticosteroids.

CALs occurred in 40.6% of the patients at their acute febrile stages. Coronary aneurysms, defined as CALs that persisted beyond 1 month of KD onset, were noted in 196 patients (18.3%, M/F=138/58): small aneurysms in 125 patients (10.3%), medium aneurysms in 44 patients (4.6%) and giant aneurysms in 27 patients (2.5%) (table 1, figure 1). Male patient was significantly associated with coronary severity at KD onset or 1 month later (p<0.01) in the early and late groups. We failed to demonstrate the association between IVIG resistance and coronary severity (p=0.38).

In the early group, coronary regression within 1 month after KD onset occurred in 54.1% (20/37) of those with IVIG and 29.7% (19/64) of those without IVIG (χ²=7.68, p=0.006), respectively. In the late group, though the percentage of coronary regression within 1 month was still higher in those with IVIG (62%, 191/308) than in those without IVIG (44.8%, 13/29), the difference was only borderline due to the small number of patients without IVIG (χ²=3.28, p=0.07).

**Long-term outcomes**

The time intervals between KD onset and the latest follow-up ranged from 1 to 46 (median 5.63) years for all patients, and from 1 to 46 (median 6.67) years for patients with coronary aneurysms. Four deaths occurred and all were male (mortality 0.4% of patients with KD, 2.0% of patients with coronary aneurysms and 14.8% of patients with giant aneurysms): one died at 3 years of age because of acute myocardial infarction (AMI), another died at 3 years of age after a heart transplant for ischaemic cardiomyopathy and the last two died suddenly at 16 and 23 years of age, respectively. All four had giant aneurysms. The 10-year and 35-year survival rates of all patients with KD were 0.99 and 0.98, respectively.

Regarding the late coronary outcomes, among the 877 patients without initial CAL or with transient dilatation, none experienced cardiac symptoms or had any positive imaging of CAL during the follow-up (6994 patient-years). Among patients with coronary aneurysms, the coronary aneurysms persisted in 31.4% of the patients during follow-up. The probability with persistent coronary aneurysm at 5 and 10 years after KD diagnosis were 27.4% and 20.6%, respectively (figure 2A). Univariable survival analysis conducted by log-rank test revealed coronary severity 1 month after onset (χ²=80.73, p<10⁻⁴) and the era of diagnosis (after 1996, χ²=4.99, p=0.025) was associated with the persistence of coronary aneurysms. Further stratified by the coronary severity 1 month after onset, the factor of diagnosis era (after 1996 vs before 1996) lost its association with aneurysm persistence (χ²=0.068, p=0.795). Myocardial ischaemia, AMI or death occurred in 14 patients, and only one was female (14/196=7.1%; 13 had giant aneurysms and one had a medium aneurysm). All types of ischaemia event-free rates at 10 and 20 years after KD diagnosis were 87.5% and 73.3%, respectively. Univariable analysis showed two possible risk factors: the severity of the coronary aneurysms 1 month after KD onset (χ²=33.46, p<10⁻³) and the diagnosis era (after 1996, χ²=6.43, p=0.01). Further stratified by the coronary severity 1 month after onset, the factor of diagnosis era lost its association with ischaemia events (χ²=3.71, p=0.054).

To avoid the potential confounding effects of coronary severity, we stratified our cohort into three subgroups based on coronary severity 1 month after KD onset and evaluated the roles of IVIG therapy and gender on the late persistence of coronary aneurysms.

**Patients with giant aneurysms (27 patients, M:F=23:4)**

None of the giant aneurysms regressed during follow-up. In the subgroup of patients with KD with giant aneurysms, the 5-year and 35-year survival rates were 0.92 and 0.69, respectively. Except for the four deaths, four additional male patients were diagnosed with AMI, and two of these diagnoses occurred within 1 year of KD onset. Collectively, the incidence of AMI or death in patients with giant aneurysms was 26%, and 67% of the AMI occurred within the first year of KD onset. Clinical evidence of ischaemia as documented in nuclear medicine studies was also noted in a further five patients (18.5%), and only one was female. Kaplan-Meier curves for survival free of AMI/death and free of all ischaemia (including ischaemia, myocardial infarction and ischaemia-related death) in patients with KD with giant aneurysms are shown in figure 3A. B. AMI/death-free survival rates were 0.76 and 0.69 at 10 and 20 years after KD onset, respectively (figure 3A). Ischaemia event-free survival rates were 0.63 and 0.36 at 10 and 20 years, respectively, after disease onset (figure 3B). Men tended to have AMI and ischaemia, and only one ischaemia patient was female. Five-year ischaemia event-free survival rates were 0.68 and 0.75 in patients with giant aneurysms with KD with and without IVIG, respectively. We did log-rank tests but failed to demonstrate an association of all ischaemia with the gender (χ²=1.01, p=0.32) or IVIG therapy (χ²=1.51, p=0.22).

**Patients with medium aneurysms (44 patients, M:F=34:10)**

In those with medium aneurysms, no death occurred and only one patient with persistent coronary aneurysm and stenosis/calciﬁcation had clinical evidence of myocardial ischaemia. However, coronary aneurysms persisted in 24 (54.5%) patients and were associated with stenosis in 8 patients (14.8%), and

Calciﬁcation in 4 patients (9.1%). The coronary aneurysm persistence probability at 6 months, and at 1, 2 and 5 years after KD onset was 81%, 74%, 60% and 46%, respectively (ﬁgure 2B). Ten of the 50 patients with medium aneurysms had aneurysms larger than 6 mm. The chances of coronary persistence and the development of stenosis or calciﬁcation were similar to patients with aneurysms between 4 and 6 mm. The 5-year coronary aneurysm persistence probability in patients with IVIG and in those without was 49% and 39%, respectively. We did not identify any coronary persistence risk factors in this subgroup (male $\chi^2=0.09$, $p=0.77$; IVIG use $\chi^2=0.45$, $p=0.50$).

Patients with small aneurysms (125 patients, M:F=81:44)

In patients with small aneurysms, only one patient reported chest pain that was associated with T-wave inversion without cardiac enzyme elevation. However, the imaging including CT, cardiac catheterisation and nuclear medicine results was all negative, suggesting resolved coronary aneurysm morphology. Coronary aneurysm persisted in 11 patients (8.8%), mostly in patients with a short follow-up. The probability of small coronary aneurysm persistence at 6 months, and at 1, 2 and 5 years after KD onset was 55%, 31%, 20% and 6%, respectively (ﬁgure 2B). The 5-year coronary aneurysm persistence probability in patients with IVIG and in those without were 8.3% and 5.6%, respectively. No risk factors were identiﬁed to predict coronary persistence (IVIG therapy $\chi^2=0.19$, $p=0.91$; gender $\chi^2=0.24$, $p=0.63$).

To avoid the error of classifying those patients with KD with a naturally dominant right coronary artery system into the small aneurysm subgroup, we further examined the 125 patients with a small aneurysm and found that 10 of them were right coronary artery dominant. The coronary aneurysms of the right coronary artery in these 10 patients regressed to the normal range during follow-up. Therefore, such misclassiﬁcation did not happen in the current study.

DISCUSSION

IVIG is the standard therapy for acute KD, and this study demonstrated that, among patients with CALs, coronary regression within 1 month after KD onset is more likely to be observed in patients with IVIG. However, IVIG use did not further modify the late coronary outcomes, including the aneurysm persistence, AMI/death events and ischaemia. Pathology studies of patients with KD have demonstrated that mononuclear cell inﬁltration in the coronary vessel walls only predominate within 40 days after KD onset.12 13 Thereafter, abundant smooth muscle cells
substitute together with vascular remodelling and collagen accumulation. Such clinical and pathology findings suggest that the immunomodulation by IVIG or any other agents should be aggressively delivered as early as possible to improve the coronary severity within 1 month after disease onset.

Our hospital is a tertiary care centre, so referral bias may occur and explain why the incidence of coronary aneurysms (17.4%) in this study was higher than those estimated from the Taiwan National Health Insurance database (8%) and a Japanese nationwide survey (4–8%). Giant aneurysms were noted in approximately 2.5% of our patients, which was similar to the incidence rates reported by the Canadian institutes (1.9–2.2%).

In Japan, the incidence of giant aneurysms was 1.04% in 1993–1994 and decreased to approximately 0.2–0.5% recently, possibly because of the earlier detection of KD and aggressive immunomodulation for patients with IVIG resistance, or a bias of the study cohort (institutional vs national cohort).

The long-term prognosis for patients with giant aneurysms is guarded. In our patients with giant coronary aneurysms, the aneurysms all persisted and one-fourth suffered AMI or death. AMI episodes occurred only in male patients with giant aneurysms. The odds of AMI for men could not be completely explained by the male dominance of KD occurrence (M/F=1.6).

In an early report when IVIG therapy was not available, 141 patients with KD and AMI were male. From our national cohort study, only one patient who experienced AMI following KD was female. The mechanisms responsible for the unfavourable KD odds for men during adolescence and early adulthood remain unclear. The reason could be that male patient was associated with the formation of giant aneurysms, which are risk factors of coronary ischaemia in patients with KD. Furthermore, in the prospective Coronary Artery Risk Development in Young Adults study on 3043 people aged 18–30 years, the prevalence of coronary arterial calcium in men was much higher than that in women (15% vs 5.1%). The early adult levels of risk factors were related to subsequent coronary risks. Therefore, it is possible that male patients with KD, once complicated with coronary giant aneurysms, would also increase the odds of AMI. Aggressive risk factor modification for potential coronary events in high-risk populations is recommended.

The favourable prognosis of small coronary aneurysms has been described. All small aneurysms regressed. However, giant or medium aneurysms clearly add to the cardiovascular risk and such subgroups of patients with KD need more frequent follow-up. In medium aneurysms, we observed that approximately half of the aneurysms persisted, and one-fifth of those with persistent aneurysms exhibited associated stenosis/calcification. However, these patients rarely developed myocardial ischaemia by early adulthood. A previous study demonstrated that at a 10-year follow-up, the probabilities of regression and developing stenosis of the medium coronary aneurysms were 32% and 20%, respectively. They also suggested a cut-off threshold for the development of stenosis as 6 mm for coronary aneurysms, which was not observed in this study.

MRI had been successfully applied to patients with KD for the cardiac evaluation, including the aneurysm, aneurysm, perfusion deficits and scarring. This would be a better alternative to CT, which is associated with risk from ionising radiation.

Study limitations
This study was subject to certain limitations. First, this was a retrospective study with a prolonged observation period. Therefore, the chance of early identification and treatment of KD might increase in recent years. The resolution of the echocardiography most likely increases over time, and the proportion of dilations or even small aneurysms might have been underestimated in those diagnosed in an earlier era. Better resolution of echocardiography might also result in increased detection and earlier diagnosis of KD. These would cause important lag time bias. Second, the diagnosis and timely treatment of KD may also have improved over time, and may be another contributing factor influencing the IVIG therapy widely used after the late 1990s. Third, the current study design was difficult to show the effects from aspirin dosage changed over time. Finally, the number of patients with medium and giant coronary aneurysms was 44 and 27, respectively, and was relatively small to assess the relationship between the treatment and outcomes.

CONCLUSIONS
In this longitudinal observational study of patients with KD, we observed that coronary severity 1 month after KD onset is most crucial to the late coronary outcomes, though male patient and...
IVIG therapy were both independent risk factors of initial coronary severity but were not associated with the late coronary outcomes, even in severity stratified subgroups. Aggressive risk modification for patients with KD with giant and possibly medium coronary aneurysms should be addressed.
