Lack of a significant change in caffeine metabolism in underweight children as determined by the caffeine breath test

K A Oshikoya, 1,2 H Sammons, 1 K Smith, 3 I Choona 1

ABSTRACT

Objective Limited data from pharmacokinetic studies in underweight and severely malnourished children have indicated an impaired activity of their hepatic enzymes. We used the caffeine breath test to assess the metabolising activity of cytochrome P450 1A2 (CYP1A2) enzyme in underweight children.

Methods Underweight children from the paediatric outpatient clinic, Lagos State University Teaching Hospital, Ikeja in Nigeria, were studied. After an overnight fast, 15 underweight children took 3 mg/kg labelled caffeine orally. Breath samples were collected in duplicate at −20, −10 and −1 min and at 15 min intervals for 2 h. The mean cumulative per cent dose recovered (CPDR) of labelled caffeine in the expired carbon dioxide was determined over the study period. This was repeated after 2–6 weeks of nutritional rehabilitation.

Results The mean areas under the enrichment-time curve before and after nutritional rehabilitation were 0.539±0.320 and 0.620±0.322 atom per cent excess minute, respectively. The difference between the two values was not statistically significant (p=0.528). The mean CPDR in the exhaled carbon dioxide of the underweight children over a period of 2 h was 7.56 ±4.01% and 7.95±3.68% before and after nutritional rehabilitation, respectively, and there was no significant difference in the mean values (p=0.603).

Conclusions The metabolism of caffeine was not significantly affected in underweight children compared with after 2–6 weeks of nutritional rehabilitation. This suggests that hepatic CYP1A2 metabolising activity was not significantly impaired in underweight children.

INTRODUCTION

Globally, an estimated 15% (99 million) of children aged <5 years were underweight in 2012. 1 The latest WHO nutrition survey, expressed in weight-for-age z-score (WAZ), in South-East Asia has reported moderate underweight (WAZ <−2 to −3) among 29% of children aged <5 years and severe underweight (WAZ <−3) in 12% of the same population of children. 2 The most common reason for being underweight is malnutrition due to lack of adequate food calories and nutrients. 3 The risk of death from the four major childhood infectious diseases (pneumonia, diarrhoea, measles and malaria) is significantly higher for underweight children. 4 The risk for multiple infections is higher in underweight than in well-nourished children. Drug therapy, especially the use of anti-infective agents, is therefore important in this group.

Drug metabolism may be impaired in malnourished children including those who were underweight.

Breath samples are stable and require no special preservation before analysis.

The caffeine breath test can be used to study CYP1A2 activity.
which is a cytochrome P450 (CYP1A2)-dependent reaction. After the 3-N-demethylation, the labelled methyl group enters the one carbon pool and converts to formaldehyde, formate and bicarbonate. The bicarbonate is finally exhaled as carbon dioxide. The cumulative per cent labelled-cafeine dose exhaled as carbon dioxide over a 2-h period is the gold standard for measuring CYP1A2 activity.

In a recent study, we have used the CBT to demonstrate a significant decrease in the metabolising activity of CYP1A2 in severely malnourished children. In order to gain more insight into the effect of underweight malnutrition on hepatic metabolism of medicines, we used the CBT to assess the metabolising activity of CYP1A2 in a group of underweight children, before and after nutritional rehabilitation.

**METHODS**

Fifteen underweight children were recruited from the paediatric outpatient department of Lagos State University Teaching Hospital, Ikeja. A sample size of 12 participants was considered appropriate for this study based on 90% power calculation and assuming a 2% difference in the mean±SD score of the 2 h cumulative per cent of $^{13}$C from the baseline to 2–6 weeks of restudy after nutritional rehabilitation, at a 5% level of significance, using previous CBT studies as a reference.

However, provision for dropout and withdrawal necessitated the use of a sample size of 15 participants. Inclusion criteria included participants in a stable clinical state, age ≥3 years, informed consent from the parent and assent from a participant aged ≥6 years. Exclusion criteria included participants with HIV or tuberculosis infection, on regular medications, and having hearing impairment, cerebral palsy or elevated blood pressure. Other exclusion criteria were persistent abnormal renal or liver function tests, persistent signs and symptoms of primary cardiovascular, respiratory or gastrointestinal disease.

Underweight malnutrition was diagnosed as a patient with 60%–80% of the expected weight without pedal oedema. Participants were first studied when underweight and after nutritional rehabilitation to attain over 80% of the expected weight for age.

Body weight and height of each subject were measured as described in our study in severely malnourished children. All the participants avoided caffeinated products for 20 h and fasted overnight prior to the CBT. All the CBTs were commenced at 9:00. Casilan, calculated as one-twelfth of the recommended dietary allowance of calories, was ingested at 8:30 before caffeine administration because of ethical issues surrounding fasting of the underweight children. Casilan is bland powder milk, rich in protein but very low in fat and carbohydrate. The subjects were compared when underweight and after nutritional rehabilitation; Student’s paired t test, p<0.005. All the children had reached at least 80% of their expected weight before the second breath test (table 1). Their mean height significantly increased from 115.4±16.3 cm (before nutritional rehabilitation) to 116.5±16.2 cm (after nutritional rehabilitation; Student’s paired t test, p<0.005). They were restudied after a mean period of 3.7 weeks following nutritional rehabilitation.

The mean areas under the enrichment-time curve before and after nutritional rehabilitation were 0.539±0.320 and 0.620±0.322 atom per cent excess minute, respectively. The difference between the two mean values was not statistically significant (Student’s paired t test, p=0.528).

The average cumulative per cent doses recovered (CPDR) in the exhaled CO$_2$ over a period of 2 h of the underweight children are shown in table 1. The mean CPDR was 7.56±4.01% before and 7.95±3.68% after nutritional rehabilitation, and there was no significant difference in the mean values (Student’s paired t test, p=0.603). The individual cumulative per cent labelled caffeine dose exhaled as CO$_2$ in a period of 2 h by each underweight child both before and after nutritional rehabilitation is presented in figure 1. There was greater interindividual variation seen before rather than after nutritional rehabilitation.

**RESULTS**

Analysis of the demographics and anthropometric parameters of the 15 underweight children showed that their mean age was 7.6±2.9 years. Their mean weight significantly increased from 17.9±5.6 kg (before nutritional rehabilitation) to 21.4±6.8 kg (after nutritional rehabilitation; Student’s paired t test, p<0.005). All the children reached at least 80% of their expected weight before the second breath test (table 1). Their mean height significantly increased from 115.4±16.3 cm (before nutritional rehabilitation) to 116.5±16.2 cm (after nutritional rehabilitation; Student’s paired t test, p<0.005). They were restudied after a mean period of 3.7 weeks following nutritional rehabilitation.

The average cumulative per cent doses recovered (CPDR) in the exhaled CO$_2$ over a period of 2 h of the underweight children are shown in table 1. The mean CPDR was 7.56±4.01% before and 7.95±3.68% after nutritional rehabilitation, and there was no significant difference in the mean values (Student’s paired t test, p=0.603).

The individual cumulative per cent labelled caffeine dose exhaled as CO$_2$ in a period of 2 h by each underweight child both before and after nutritional rehabilitation is presented in figure 1. There was greater interindividual variation seen before rather than after nutritional rehabilitation.

**DISCUSSION**

In the present study, underweight children were studied before and after nutritional rehabilitation. Nutritional rehabilitation for 2–6 weeks enabled the underweight children to attain the

Drug therapy

necessary for microsomal drug metabolism. Altered drug intake, resulting in reduced total microsomal haeme, phospholipids and flavin adenine dinucleotide levels, all of which are necessary for microsomal drug metabolism.

expected weight-for-height of well-nourished children before they were restudied, thus serving as normal weight controls. We have demonstrated no significant difference in labelled CO₂ exhaled over 2 h. This suggests that the metabolism of labelled caffeine was not significantly affected in children when they were underweight compared with when they had attained at least 80% normal weight after nutritional rehabilitation.

A limitation of our study is that the children were studied immediately after nutritional rehabilitation. It is possible that hepatic enzyme recovery significantly lagged behind nutritional recovery. However, our findings are consistent with those of Travanouz et al., who determined the plasma clearance (CL) of antipyrine (a drug, ie, partially metabolised by CYP1A2) in underweight adults and showed no significant change after nutritional rehabilitation.

Three other studies, in contrast, have shown decreased CL of different drugs in underweight patients. Specifically, antipyrine CL was decreased in underweight adults, while the CLs of acetylsalicylic acid and penicillin decreased in underweight children.

Different types of CYP450 enzymes are responsible for the metabolism of caffeine and acetylsalicylic acid, while penicillin is usually eliminated without undergoing hepatic metabolism. Acetylsalicylic acid is metabolised by CYP3A4, while caffeine is predominantly metabolised by CYP1A2. Variation in the activity of the metabolising enzymes may account for the differences in the disposition of caffeine and other drugs in underweight children.

The present results of underweight children are in contrast to those of severely malnourished children. CYP1A2 enzyme activity was significantly impaired in severely malnourished children with marasmus, marasmic-kwashiorkor or kwashiorkor. It is important therefore to be aware that malnutrition is a specific type of infantile malnutrition.

The mechanism involved in the altered CYP1A2 activity and decreased caffeine metabolism in severe malnutrition remains poorly understood. It has been postulated that impairment in drug metabolism in children with marasmus may be partly related to an adaptation to insufficient energy intake, resulting in reduced total microsomal haeme, phospholipids and flavin adenine dinucleotide levels, all of which are necessary for microsomal drug metabolism.

Impairment of drug metabolism in children with kwashiorkor has been attributed to maladaptation to nutritional deprivation, which includes hepatic fatty infiltration, rough endoplasmic reticulum and mitochondria deformity and reduced peroxisomes. CYP1A2 is a major metabolic pathway for caffeine, theophylline, naproxen, haloperidol and the antidepressants duloxetine and fluvoxamine. It is also a contributory metabolic pathway for many other drugs. The findings from our study suggest that dose adjustment is not necessary for underweight children who are receiving caffeine, theophylline, haloperidol, naproxen, duloxetine or fluvoxamine. It is important, however, to recognise that our findings are only relevant for drugs where CYP1A2 is a major metabolic pathway. The effect of being underweight needs to be studied separately for each of the different metabolic pathways.

In conclusion, the CBT has demonstrated no significant change in the metabolism of caffeine in underweight children. This suggests that the doses of medicines that are primarily metabolised by hepatic CYP1A2 do not need to be modified in underweight children.

Contributors KA Oshikoya conceptualized and designed the study, collected and analysed the samples, performed the data analysis and wrote the initial and final draft of the manuscript. IC and HS contributed to the conception and design of the study, reviewed the data analysis, edited and approved the final draft of the manuscript. KS contributed to the sample and data analyses and reviewed the initial draft of the manuscript.

Funding KA was, at the time of this research, a postgraduate research student at the University of Nottingham, UK. He was jointly sponsored for the postgraduate education by the Lagos State Government and Lagos State University.
