Effectiveness of hand hygiene interventions in reducing illness absence among children in educational settings: a systematic review and meta-analysis

Micky Willmott, Alexandra Nicholson, Heide Busse, Georgina J MacArthur, Sara Brookes, Rona Campbell

ABSTRACT

Objective To undertake a systematic review and meta-analysis to establish the effectiveness of handwashing in reducing absence and/or the spread of respiratory tract (RT) and/or gastrointestinal (GI) infection among school-aged children and/or staff in educational settings.

Design Randomised-controlled trials (RCTs).

Setting Schools and other settings with a formal educational component in any country.

Patients Children aged 3–11 years, and/or staff working with them.

Intervention Interventions with a hand hygiene component.

Main outcome measures Incidence of RT or GI infections or symptoms related to such infections; absenteeism; laboratory results of RT and/or GI infections.

Results Eighteen cluster RCTs were identified; 13 school-based, 5 in child day care facilities or preschools. Studies were heterogeneous and had significant quality issues including small numbers of clusters and participants and inadequate randomisation. Individual study results suggest interventions may reduce children’s absence, RT infection incidence and symptoms, and laboratory confirmed influenza-like illness. Evidence of impact on GI infection or symptoms was equivocal.

Conclusions Studies are generally not well executed or reported. Despite updating existing systematic reviews and identifying new studies, evidence of the effect of hand hygiene interventions on infection incidence in educational settings is mostly equivocal but they may decrease RT infection among children. These results update and add to knowledge about this crucial public health issue in key settings with a vulnerable population. More robust, well reported cluster RCTs which learn from existing studies, are required.

INTRODUCTION

Young children are particularly susceptible to respiratory tract (RT) and gastrointestinal (GI) infections. While usually self-limiting, these highly infectious illnesses spread quickly in semiclosed settings such as schools. Infections affect child health, causing missed educational opportunities which may have a detrimental effect on educational outcomes,1 lost productivity and days off work for school staff.2 Educational settings where large numbers of children with immature immunity congregate are promising sites for preventing infection, particularly as outbreaks can affect whole schools and spread to vulnerable populations (eg, younger siblings) in the community.3,4

Several systematic reviews (SRs) have evaluated evidence of interventions to prevent RT and GI infections;6–16 current evidence is equivocal but promising for the effectiveness of hand hygiene interventions in preventing the spread of respiratory tract and gastrointestinal infection.

What this study adds

▸ Eighteen cluster randomised controlled trials of the effectiveness of hand hygiene interventions in educational settings were identified; more than in previous dated reviews.

▸ Study design and reporting standards are generally low quality, impeding meta-analyses, but recently published studies show signs of improvements.

▸ Evidence of the impact of hand hygiene interventions among this population remains equivocal: this review makes recommendations for improving future trials to evaluate interventions.

What is already known on this topic

▸ As semiclosed settings where large numbers of children with immature immunity regularly congregate, educational establishments are potentially effective places to prevent spread of infection.

▸ Evidence is equivocal but potentially promising for the effectiveness of hand hygiene interventions in preventing the spread of respiratory tract and gastrointestinal infection.

▸ Three systematic reviews of studies of hand hygiene interventions to prevent respiratory and/or gastrointestinal infections focus on educational settings; each has significant limitations.
transmission from young children through regular education at school on hygiene.” (ref.11, p.9).

Three SRs,12 13 16 focus exclusively on studies among children in educational settings. However, one only included hand sanitiser interventions;14 another included children 2–11 years old and is over a decade old.16 The most recent SR focused on the effects of multicomponent interventions (access to safe water, handwashing facilities, hygiene education) but did not assess study quality, included numerous study designs and had limited search parameters (eg, only searched in two databases).12 None of these SRs included meta-analyses (MAs). This review aimed to update these reviews using thorough methods (eg, searching a range of databases) to identify all relevant studies which apply the most robust study design (randomised controlled trial, RCT) for evaluating interventions.

The objective of this SR was to summarise evidence of the effectiveness of hand hygiene interventions in reducing infectious illness and/or absence in educational settings for children aged 3–11 years and/or staff working with them, and to obtain a quantified estimate of the effect using MAs if possible.

METHODS
This SR is reported in line with current guidance.17 Review coauthors agreed the review protocol.18

Eligibility criteria
This SR included RCTs of interventions with a hand hygiene component (any comparator) in educational settings for children aged 3–11 years in any country. No length of follow-up was defined.

Educational settings were defined as institutions incorporating formal educational activities including day care facilities and nurseries. Other community settings (eg, playgroups) and domestic child care settings were excluded. Study populations could include staff and/or children in these settings. The review age range aimed to ensure the inclusion of all studies in formal educational settings for younger (primary or elementary school-aged) children—hereafter referred to as primary school-aged children—where children can be expected to understand hand hygiene, toilet themselves and clean their own hands. Study populations could include children whose age overlapped with the review age range (eg, 2–6-year-old, 5–12-year-old) because school policy and practice varies between countries: children start formal education at different ages; children may repeat a year so may be older than 11 years in primary school; structured nursery facilities for younger children may be integrated in schools.

Hand hygiene interventions were defined as any initiative for children and/or staff working with them undertaken to prevent the spread of infectious illness. Comparators could include placebos or active comparators such as handwashing with soap compared with hand sanitiser use.

Inclusion criteria were pilot ed on reports known to authors.

Primary review outcomes were: incidence of RT or GI infections or symptoms related to such infections; absenteeism rate; or laboratory results of RT and/or GI infections. Secondary outcomes were: hospital admissions due to such infections; changes in knowledge, attitudes, beliefs or behaviours about hand hygiene among children and/or staff working with them. We intended that outcomes related to children and staff be considered separately: we did not anticipate many studies would report staff outcomes. Studies which presented outcome data for staff and children together would be considered separately from studies which presented data for staff and students.

Information sources and search strategy
The search strategy had three components: handwashing, population and setting and study type. Handwashing, population and setting terms were extensive; handwashing terms used free-text terms as well as available controlled vocabulary terms. Population and setting terms were not used in education databases (Education Resource Information Center, Australian Education Index, British Education Index). The search focused on sources reporting RCTs and excluded unpublished literature as the coauthors agreed this was unlikely to report RCTs. A broad study type filter was used in databases where RCTs were less well indexed (see figure 1 for MEDLINE search strategy). No date or language restrictions were applied.

Eight electronic databases were initially searched from inception to April 2011: MEDLINE (1950 to date), EMBASE (1980–2011, week 15), Social Science & Science Citation Indexes (ISI Web of Knowledge), CINAHL, Cochrane Library, Education Resource Information Center (1966 to date), Australian Education Index (1979 to date) and British Education Index (1975 to date). The search was updated twice using the same strategy, first to cover up to 26 September 2012, then up to 5 September 2014; dates overlapped with previous searches to ensure items were not missed. Results of each search were uploaded to an EndNote database, combined and deduplicated.

Study selection and data collection process
All titles were screened for eligibility by one reviewer; 10% were independently screened by a second reviewer (Cohen’s x statistic=≥0.75). Absents were independently screened by two reviewers. Where reviewers did not agree, abstracts were included in full paper screening. Full papers were dual reviewed and reasons for exclusion recorded: coauthors moderated where there was disagreement. Additional studies were identified through references in full papers and citation search facilities in ISI Web of Science, journal websites and Google Scholar.

Two potentially eligible abstracts not in English were reviewed by native speakers. A full translation was obtained for the one study that met review criteria.19 Protocols for included studies were obtained from trial registers where available.

Data collection and data items
Two reviewers independently extracted study data using a form developed from a template from another SR and piloted on a sample of included studies. Data included were: study details; intervention description; study recruitment; random allocation; study baseline data; follow-up; process evaluation; outcomes and analysis. Reviewers discussed differences and recorded moderated results.

Risk of bias assessment
Study quality was assessed independently by two reviewers using the Cochrane Risk of Bias tool (V5.1), compliance with reporting guidance20 21 and good research practice (research governance, process evaluation, outcome measurement methods) pertinent to interventions with this population in these settings.

Summary measures
All effect measures pertaining to review outcomes are reported. Where studies included children under 3 years old and stratified the results they presented by age, we only report results for children over 3 years old. Where possible we present unadjusted results, where adjusted results are stated the variables used for adjustment are described. As a large number of studies reported
absence by reason, three additional sets of outcome data are presented; absence due to any illness, absence due to RT infection, absence due to GI infection.

Synthesis of results
We aimed to conduct MAs if studies were sufficiently homogenous and data were adequate. Missing and unclear data were identified in the data extraction form. Studies where additional data could not be accessed were excluded from MA and reasons recorded. Authors were only contacted in exceptional circumstances due to the length of time since completion for many studies. No authors provided additional data. This led to the exclusion of several studies. Six studies were excluded due to design flaws (risk of contamination between study arms); crossover design, clusters at class level and clusters at class and school levels. Therefore, MAs were not conducted.

Additional analyses
Prespecified subgroup analyses (age, gender, location, setting, intervention and duration) and sensitivity analyses were not possible due to poor reporting and data quality.

RESULTS
Study selection
Of the 5,306 titles assessed for eligibility, 18 studies fitted review criteria (Figure 2). Protocols for four RCTs with as yet unpublished results were identified. 29–32

Study characteristics
All included studies were cluster RCTs, including two with a cross-over design 22,23 (Table 1).

Study participants
Age of participating children was not always reported. Five of the 13 school-based studies included all children in each school, others included one or more age grade. Six studies included children under 3 years. 19,24,37,46,47,53 These were retained because the interventions included hand hygiene for children as well as staff. Four studies included students over the typical maximum primary school age of 11 years. 27,34,36,37 These were retained because students’ education level was likely to be equivalent to students in other contexts.
Country location and setting
Thirteen studies were school-based; five were in day care facilities or preschools. Institutions were not necessarily representative of settings in that country. For example, one study only included schools with continuous water supply.45 Eleven studies were in high-income countries (defined using World Bank categories54); only two did not involve hand sanitiser.19 48 Four studies were from middle-income countries;24 33 45 46 three were from one low-income country (Kenya).34 36 37

Interventions and comparators
Twelve interventions included hand sanitiser;22–27 37 39 41 46 47 53 six focused on handwashing with soap.19 33 34 36 45 48 Several interventions included additional infection control measures, such as eliminating shared cups,48 water treatment and building new latrines,34 36 cleaning toys or equipment.25 53 Five included a home component such as parental information.19 33 41 45 48

Fourteen studies compared interventions with ‘standard practice’ but this was often unclearly defined. One study was placebo-controlled,26 three compared an intervention with an alternative intervention.23 36 39 Four studies compared two interventions and a control.24 33 34 37 Only two studies adopted a multifactorial design to test the effect of different intervention components.24 37

Hand hygiene protocols varied. For example, only 7 of the 12 studies including hand sanitiser described the frequency and/or intensity of use. Nine interventions lasted 10 weeks or less.19 22 23 25 26 33 34 37 48

Outcomes
The online supplementary table S2 presents study results according to review outcomes. Only three studies34 37 41 46 48 did not report absence outcomes. Six studies presented knowledge, attitude and/or behavioural outcomes.34 36 37 41 48 53 No study reported hospital admissions due to infection. Four studies presented staff outcomes.36 37 48 53

Outcome definitions and summary measures varied. Three reports did not clearly define illnesses or symptoms.23 47 48 Some only reported adjusted outcomes (variables differed between studies).

Risk of bias within studies
Methodological issues increased risk of bias in most studies (see online supplementary table S1, reviewers’ assessment of the quality and risk of bias of included studies). Some issues highlight difficulties in evaluating behaviour change (eg, lack of participant blinding); others indicate study design weaknesses (eg, random sequence generation) and inadequate reporting (eg, only reported statistically significant results).

Five studies described an adequate method of random sequence generation,39 41 45 46 53 only two adequately described allocation concealment.19 41 Perhaps unsurprisingly given the nature of the intervention, only the study where a placebo hand sanitiser was the comparator was judged to be at low risk of performance bias.26 Only one study39 was assessed as having adequately described all measures to blind outcome assessors. The completeness of data reported for each outcome was assessed as adequate in five studies;23 24 25 33 46 48 a high risk of selective reporting was identified in four studies.24 26 37 41

Four reports did not present baseline data.19 22 23 26 Despite being concerned with illness outcomes, only eight reported baseline health data.24 25 27 33 46 48 53

Six studies22–28 had clusters at class level (two of these applied a cross-over design), therefore increasing risk of contamination between study arms. Not all investigators took clustering into account in sample size calculation or analysis.

Three studies were funded by companies producing hygiene products,23 25 33 three used manufacturer-donated products,22 37 46 one required parents to provide soap and hand

RCT, randomised controlled trial; WASH, Water, Sanitation and Hygiene.
drying materials. It is unclear whether the way in which these interventions were resourced affected their acceptability, sustainability or study outcomes: only two study reports state the role of these companies in the study, analysis and report.

Most reports described the intervention protocol and monitoring, three noted intervention costs but few presented process evaluation data.

Most outcome measurement methods could have introduced bias due to poor case definition, use of non-validated tools or self-report (including routine school absence reporting data). Some studies which attempted to validate outcomes (eg, illness) experienced attrition due to the complexity of the process (ref. 41, p.3).

**Individual study results**

Five of the six studies reporting children’s absence and 8 of the 13 studies measuring children’s illness absence reported an intervention effect (see online supplementary table S2 for study results according to review outcomes). The one study reporting staff illness absence found it was higher among the intervention group which may be because the intervention included asking staff not to attend work if they had infection symptoms.

All five studies reporting RT infection incidence showed a reduction, but each applied different outcome definitions. Three reported RT infection symptoms (rhinitis, cough); one found a reduction in both, one only identified a reduction in observed rhinorrhea and another found no change in cough and a 12% increase in rhinorrhea episodes (‘standard’ intervention vs control).

Two studies reported GI incidence; one reported a reduction,66 the other did not.53 Only one of three studies recording diarrhoeal symptoms found any effect.57 Two studies reported vomiting outcomes only one found an effect.53

Two studies collecting laboratory results found evidence of decreased ILI, although in one study this only related to influenza A (ref. 41, Supplemental Digital Content (SDC) 2).

Four of five studies reporting children’s behaviour change identified a positive intervention effect. All five studies reporting changes in children’s and/or staff hand hygiene knowledge, attitudes and/or beliefs found an intervention effect.

**Synthesis of results**

Due to study heterogeneity and the generally low quality of study design and of study reporting, coauthors agreed that it could be misleading to present pooled estimates of the effect of interventions using MAs.

**DISCUSSION**

**Main findings**

We found 18 cluster RCTs investigating the effect of interventions with a hand hygiene component on absence and infection among 3–11-year-old children in educational settings. Individual study results suggest interventions may reduce children’s absence, RT infection incidence and symptoms, and laboratory-confirmed ILI. They may also improve children’s and staff hand hygiene attitudes, knowledge and behaviour. Evidence of impact on GI infection or symptoms was equivocal.

Despite updating existing SRs and identifying new studies, individual study results appear to show that there remains equipoise about the effectiveness of hand hygiene in preventing RT and GI infection.

**Strengths and limitations of this review**

Much has been made of the potential of hand hygiene interventions for reducing infection in this population. This review provides a more detailed assessment of such interventions and how promising they might be based on studies which apply the most rigorous RCT evidence. This review updates existing SRs focused on this population, and our comprehensive search strategy resulted in finding more studies than previous SRs. Findings of this review corroborate existing SRs; that studies have significant design limitations and poor quality reporting. The quality of reporting in more recently published studies seems to have improved which perhaps indicates the impact of guidance on the reporting of cluster RCTs. This may result in improved evidence, capable of demonstrating the effectiveness of this important public health issue. Despite identifying new studies, it was not possible to produce meaningful MAs (as earlier SRs have found) due to study heterogeneity, study design limitations and poor quality reporting.

Limitations of this SR include that: we assumed that report titles or abstracts would contain ‘handwashing’ or ‘hands’ but they did not; unpublished literature was excluded; some included studies had study populations which included children younger and older than the prespecified review age range; RT and GI infection incidence can vary within the age range included in the review, as can the potential effectiveness of interventions (due to children’s developmental stage); risk of bias assessment was impeded by inadequate reporting. Furthermore, all interventions with a hand hygiene component were included so the impact of hand hygiene cannot be isolated. This review does not distinguish between handwashing with soap or hand sanitiser use even though these methods may have different resource implications and be differentially effective in eliminating certain pathogens.

**What this study adds**

While studies are heterogeneous, there is evidence that hand hygiene interventions among primary school-aged children in educational settings may be beneficial, particularly in reducing RT infection incidence. However, this SR highlights limitations of evidence on this crucial public health issue in a key setting with a vulnerable population and the need for improved studies to enable more definitive assessment (eg, MA) of the effectiveness of simple public health interventions to inform practice. We have four recommendations for future research and which may enable future estimates of the pooled effects of such interventions using MA.

First, better designed and reported cluster RCTs are required. Investigators should apply guidance and learn from robust studies in order to avoid design flaws (eg, clusters at classroom level) and improve reporting (eg, children’s age, control group conditions). Second, studies should incorporate technical advances for outcome measurement, such as the use of environmental swabs to detect the level of viral and/or bacterial contamination in schools which may enable robust, standardised outcomes instead of using self-report and observations. Third, research should include process evaluation to refine interventions and establish intervention acceptability and fidelity. Studies which have done process evaluations have identified barriers to hand hygiene including access to adequate sanitary facilities (even in high-income countries), suggesting that provision of hygiene products and education may be insufficient to achieve effective infection prevention and control and more robust studies of complex, multicomponent interventions are required. Fourth, studies should evaluate cost, cost-effectiveness and intervention sustainability in educational settings.
CONCLUSION
Interventions to improve hand hygiene in educational settings may reduce RT infection incidence among younger children. More robust, well reported studies are required, especially of multicomponent interventions.

Contributors The manuscript has been read and approved by all authors. RC, SB, AN conceived and instigated the study. RC, SB, AN and MW drafted the protocol. MW conducted the 2014 search and all citation searches. MW, QIM and AN screened the results. MW, AN and HB extracted the data and assessed the quality of studies. RC and SB were moderators. MW and RC analysed the data. MW drafted the manuscript for publication. All authors contributed to this report and subsequent revisions. Each author believes that the manuscript represents honest work.

Funding This work was undertaken with the support of NIHR Research for Patient Benefit Grant (PB-PG-1207-15212) and of The Centre for the Development and Evaluation of Complex Interventions for Public Health Improvement (DECIPHer), a UKCRC Public Health Research Centre of Excellence. Joint funding (MR/KO232331/1) from the British Heart Foundation, Cancer Research UK, Economic and Social Research Council, Medical Research Council, the Welsh Government and the Wellcome Trust, under the auspices of the UK Clinical Research Collaboration, is gratefully acknowledged. Views expressed in this paper do not represent those of the funders. The funders had no role in study design, data collection and analysis, decision to publish or manuscript preparation.

Competing interests None declared.

Provenance and peer review Not commissioned; externally peer reviewed.

Data sharing statement Additional unpublished data from the study (data extraction forms, attempted meta-analyses) are available on request from the corresponding author.
