ABSTRACT

Background Coeliac disease (CD) incidence has increased in recent decades, characterised by variations according to sex, age at diagnosis, year of birth, month of birth and region of birth. Genetic susceptibility and exposure to gluten are the necessary factors in CD aetiology, although several environmental factors are considered.

Methods A nationwide prospective cohort longitudinal study was conducted consisting of 1 912 204 children aged 0–14.9 years born in Sweden from 1991 to 2009. A total of 6569 children were diagnosed with biopsy-verified CD from 47 paediatric departments. Using Cox regression, we examined the association between CD diagnosis and season of birth, region of birth and year of birth.

Results Overall, CD risk was higher for children born during spring, summer and autumn as compared with children born during winter: adjusted HR for spring 1.08 (95% CI 1.01 to 1.16), summer 1.10 (95% CI 1.03 to 1.18) and autumn 1.10 (95% CI 1.02 to 1.18). Increased CD risk was highest if born in the south, followed by central Sweden when compared with children born in northern Sweden. Children diagnosed at <2 years had an increased CD risk if born in spring while those diagnosed at 2–14.9 years the risk was increased for summer and autumn births. The birth cohort of 1991–1996 had increased CD risk if born during spring, for the 1997–2002 birth cohort the risk increased for summer and autumn births, while for the birth cohort of 2003–2009 the risk was increased if born during autumn.

Conclusions Season of birth and region of birth are independently and jointly associated with increased risk of developing CD during the first 15 years of life. Seasonal variation in infectious load is the likely explanation.

INTRODUCTION

Coeliac disease (CD) is an immune-mediated enteropathy with a multifactorial aetiology.¹ Only persons ingesting gluten and expressing human leucocyte antigen (HLA) DQ2 or DQ8 can develop CD.¹ Apart from gluten other environmental factors have been suggested including: mode of delivery, infant feeding, gut microbiota, infections, socioeconomic status and season of birth, though evidence is contradictory.^{2–7} Several studies have shown that spring/summer birth is more common in patients with CD compared with their healthy counterparts^{8–11} suggesting a role of seasonal exposures. A seasonal pattern has also been shown for type 1 diabetes,¹² in children with a double

What is already known on this topic?

- ▶ Coeliac disease (CD) is increasing worldwide suggesting environmental factors in the aetiology.
- ▶ CD incidence varies with sex, age at diagnosis, year of birth, month of birth and by geographical location.

What this study adds?

- ▶ Spring births was associated with increased coeliac disease (CD) risk if diagnosed before 2 years of age while summer and autumn births were associated with high risk if diagnosed after 2 years of age.
- ▶ CD risk is higher in southern Sweden compared with the north with differences in seasonal incidence pattern.
- ▶ Seasonal viral infections during a vulnerable period of immune development are the likely explanation to observed seasonality but does not explain geographical differences.

diagnosis of CD and type 1 diabetes⁶ and, in other immune-mediated diseases.¹³ Viral infections have a seasonal pattern and have also been associated with increased CD^{5–14} and type 1 diabetes risk.¹⁶

In areas of high latitude such as Sweden, a seasonal pattern in exposure to sunlight and ultraviolet-B (UV-B) radiation is an exposure of interest. UV-B is needed for the synthesis of vitamin D in the skin yet in higher latitudes little vitamin D is synthesised during winter thus populations depend on dietary vitamin D or supplementation. Vitamin D deficiency might be associated to seasonal variations in birth seen in autoimmune diseases including CD. It has also been suggested that vitamin D supplementation could contribute to increased CD risk.¹⁷ Geographically, Sweden stretches about 1570 km from north to south, lying between latitudes 55° and 69° North. Southern Sweden is characterised by intense sunlight in spring and summer, while in northern Sweden spring is generally colder and summer is shorter.¹⁸

We have reported geographical variation in CD both in clinical and screening studies.^{19–21} Pronounced variations in CD incidence was

observed between birth cohorts during the CD epidemic (1985–1995) and postepidemic years, possibly related to variations in environmental exposures.²² The objective of this study was to explore the effects of season of birth on the risk of CD comparing different areas and time-periods in order to generate hypotheses about environmental factors associated with CD seasonality.

METHODS

The study used a prospective cohort longitudinal design with data obtained through the Swedish national registers, accessed through the Umeå SIMSAM Lab (SIMSAM: Swedish Initiative for Research on Microdata in the Medical and Social Sciences).²³ Individual data obtained from Statistics Sweden and the Swedish National Childhood CD Incidence Register was linked using the Swedish personal identity number.²⁴

The study consisted all children aged 0–14.9 years, born between 1991 and 2009. A total of 1 912 204 children were identified of which 6596 were diagnosed with CD, from 47 paediatric departments. CD diagnostic criteria were a small intestinal mucosa with villous atrophy, according to the 1990 European Society for Paediatric Gastroenterology, Hepatology and Nutrition criteria.²⁵

Definition of explanatory variables

Season of birth was classified according to four seasons: winter (December, January, February), spring (March, April, May), summer (June, July, August) and autumn (September, October, November). Region of birth was classified according to the Swedish national areas of the nomenclature of territorial units for statistics (NUTS 1), a geocode standard developed by the European Union for referencing administrative divisions of countries for statistical purposes. Age at diagnosis was defined as age when the first positive small intestinal biopsy was obtained and was estimated in years, divided into two categories: 0–1.9 (children <2 years) and 2–14.9 years (children between 2 and <15 years of age). Year of birth was categorised into four birth cohorts; the cohort of 1991–1996 represented children born during CD epidemic, 1997–2002 included

children born immediately after the epidemic and 2003–2009 were born after the epidemic had abated.

Statistical analysis

Average CD incidence rates were calculated per month of birth and region of birth by dividing the number of cases diagnosed by the number of person years of follow-up, and reported per 100 000 person years. Cox proportional hazard regression models were used to estimate the HR for CD diagnosis. For CD cases we considered age at diagnosis, while non-cases were considered censored at 15 years of age (the highest age included) or age at the end of the study follow-up (31 December 2009). The proportional hazards assumption for the independent variables was tested graphically with Kaplan–Meier curves. Bivariable (unadjusted) analyses were performed to explore the associations between CD and each of the explanatory variables. In the multivariable analysis (adjusted), each variable was adjusted for other studied factors. Both analyses were repeated while stratifying for age, region and birth cohort. Interaction was investigated for independent variables as cross terms pairwise in the adjusted model and checked for significance. Incidence rates were calculated using Microsoft Excel 2008 (V.12.3.2) and Cox proportional hazard was done using SPSS V.22.0 for Windows (SPSS, Chicago, Illinois, USA).

Ethical considerations

The Regional Ethical Vetting Board in Umeå approved research based on data obtained from the Umeå SIMSAM Lab.

STUDY FINDINGS

Characteristics of the study population

The total number of children, irrespective of their CD status is given in relation to season and region of birth and sex in table 1. The proportional hazards assumption was fulfilled for all studied variables and no significant interaction between independent variables and CD was found (results not shown). CD risk was higher for children born during spring, summer and autumn as compared with children born during winter. After adjusting for region of birth and sex, the effect of season of birth remained the same as observed in the unadjusted model,

†Multivariable: regression with all independent variables.

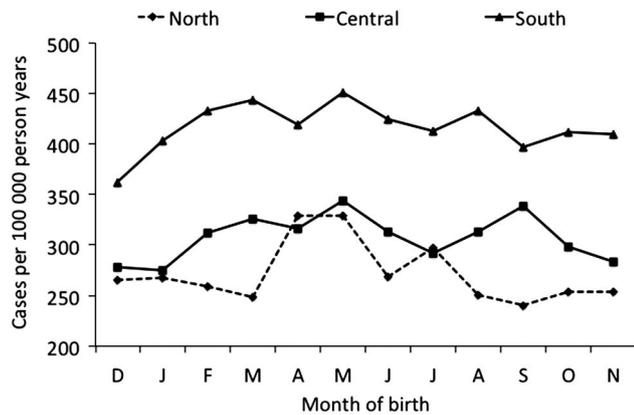

Figure 1 Coeliac disease incidence rate by month of birth in children aged 0–14.9 years during the period from 1991 to 2009 for the three nomenclature of territorial units for statistics (NUTS 1) regions in Sweden.

except for minor changes. In the unadjusted and the adjusted analyses, the risk of developing CD was lowest in northern region compared with southern and central Sweden. CD risk was more pronounced in girls in both unadjusted and adjusted analyses (table 1).

CD incidence rate in relation to region and season of birth

The incidence rate pattern for the NUTS regions differed by month of birth as shown in figure 1. In northern Sweden, the incidence rate was low throughout the year except for an increase in April and May. In central Sweden, an increase in CD incidence began in February to May. In the remaining months of June to November, the incidence rate appeared to drop aside from an increase in August. In southern Sweden, December to May were marked by a gradual increase, except for a decrease from June to November.

CD risk in relation to region and season of birth stratified for age

Among children below 2 years of age, CD risk was higher when born during spring compared with winter, no major differences were observed for other seasons, region of birth was not associated with CD risk (table 2). Children 2–14.9 years born during summer and autumn had an increased CD risk compared with those born during winter. This age group had the highest risk if born in southern Sweden, followed by central Sweden. This effect remained after adjusting for season and sex (table 2). CD risk was higher in girls than in boys regardless of age, although children aged 2–14.9 years had higher OR (table 2).

CD risk in relation to region and season of birth stratified by birth cohort

Among children born 1991–1996 the risk of developing CD was significantly increased if born during spring compared with winter. In the 1997–2002 birth cohort, CD risk was increased if born during summer and autumn. In the 2003–2009 cohort, CD risk was increased if born in autumn compared with winter (table 3). For children born between 1991 and 1996, the risk was increased for central and southern Sweden compared with northern Sweden. For children born in 1997–2002, increased CD risk was associated to being born in southern Sweden compared with the north, no association was observed for those born in central Sweden. Among children born between 2003

and 2009, the risk was increased for both central and south births compared with northern births (table 3). Girls had higher risk compared with boys in all years. The risk was highest among girls in the 2003–2009 birth cohort, followed by the birth cohort of 1997–2002 (table 3).

DISCUSSION

Spring birth was associated with increased CD risk in children diagnosed before 2 years of age while summer and autumn births were associated with high risk in children diagnosed after 2 years of age with noticeable changes over time. Seasonal pattern differed between regions, with increased CD incidence rates in southern Sweden from December to May. In central Sweden the increase started in February, while in north this started later and was more pronounced than in other regions. Stratification by age at diagnosis showed spring births to be associated with increased CD risk in children diagnosed before 2 years of age while summer and autumn births were associated with high CD risk in children diagnosed after 2 years.

One of the limitations of this study is lack of data on infections and vitamin D level, thus at the moment inference on how these might influence seasonality and subsequently CD risk remains speculative and calls for further investigation. CD risk may have been underestimated because CD cases without a PIN code were excluded. Lacking a PIN code was mainly due to not seeking parental consent, also a few declined to participate. Underestimation of CD risk is also possible since Marsh 3 was the standard for CD diagnosis; by implication potential cases, that is, with Marsh 1–2 or with elevated serological markers were excluded.

This is the first Swedish study investigating CD risk while taking into account four seasons and looking at geographical variations. The association between season of birth and CD has been the subject of several studies from Sweden. The first study followed children up to 1997, and found summer to be associated with increased risk in children diagnosed before the age of 2 years.⁸ Lebwahl *et al* using Swedish pathology data showed a slightly increased risk in adults born during summer.⁹ Lewy *et al* reported increased CD risk in girls born during summer and in children diagnosed before 2 years of age but not in boys or in older children.¹⁰ A US study reported spring birth to be associated with increased CD risk in boys younger than 15 years of age at diagnosis.¹¹ All evidence supports a seasonal environmental exposure in CD aetiology except for one Finnish study.²⁶

Children born in southern Sweden had the highest CD risk, followed by central and the lowest in northern Sweden. The Swedish population is considered genetically homogenous with >50% prevalence of HLA risk genes.²⁷ Consequently, geographical differences in CD risk are not fully explained by genetic clustering, suggesting the role of other environmental factors. Interestingly, CD is associated with acute viral infections like rotavirus, astrovirus and adenovirus and other viral infections.^{5 14 15 28} One hypothesis for increased CD risk and spring/summer birth is that, those infants are more likely to be weaned and introduced to gluten during autumn/winter, a time characterised by exposure to seasonal viral infections. Some studies suggested breast feeding to be protective against CD³ and there are several possible mechanisms for this including a modulatory effect on gut microbiota and its direct effect on the immune system.²⁹ However, more recent studies could not confirm breast feeding's protective effect.^{4 30–33} Viral infections influence the intestinal microbiota, the barrier function and

Season of birth is grouped as follows: winter (December, January, February), spring (March, April, May), summer (June, July, August) and autumn (September, October, November). Region of birth is grouped according to the administrative division of nomenclature of territorial units for statistics (NUTS 1) regions.

increase mucosal permeability, which might be the mechanism of action in CD pathogenesis; however, this requires further investigation.³⁴

In the north, the high incidence period started later compared with the south and central parts of Sweden. Geographical difference in awareness is a possible explanation, though it cannot fully explain these variations since our previous screening studies reported a similar pattern between north and south as reported in this paper with a 1/3 prescreening detection rate in all regions.²⁰ Among Swedish physicians, it is known that the yearly epidemics of respiratory syncytial virus, rotavirus and influenza start in southern Sweden and spread northwards over a couple of months,³⁵ which supports our findings. Moreover, there is a difference in distribution of rotavirus genotypes between Swedish regions.³⁵

Another suggested mechanism for seasonal variation in CD risk is vitamin D deficiency due to differences in sunlight and UV-B exposure.³⁶ Suboptimal levels of vitamin D during early

childhood are a risk factor for immune-mediated diseases including multiple sclerosis, inflammatory bowel disease and type 1 diabetes mellitus.^{13 37} Sweden has large regional differences in sunlight and UV-B exposure,³⁸ thus the low CD risk in the north does not support this hypothesis as this region receives few hours of sun exposure throughout the year. Moreover, in Sweden every child is recommended and offered government-funded vitamin D supplementation from 1 week to 2 years of age, ensuring adequate levels. A remaining possible link to sunlight and vitamin D is that pregnant women who give birth in spring have the lowest levels of vitamin D during late gestation when important programming and development of the fetal immune system takes place.³⁹ Another hypothesis suggests increased CD risk due to high levels of vitamin D; this fits the situation in south Sweden.¹⁷ This hypothesis is still new and is based on comparisons between countries. Tanpowpong and Camargo suggested a model where introduction of gluten, low levels of vitamin D and exposure to viral infections are

responsible for the seasonal effect;³⁶ whether this model is plausible remains to be confirmed.

CONCLUSION

We have confirmed a statistically significant effect of season of birth on the risk of being diagnosed with CD during childhood with the highest CD risk if born in south Sweden. Viral infections are the strongest possible risk factor in favour of our findings, although the role of vitamin D during pregnancy is still plausible. Whatever exposures are important in explaining seasonality, they have to work in a well-defined period, that is, during early life when the immune system is in an important developmental phase, otherwise there would be no seasonal pattern.

ARCHIVES OF DISEASE IN CHILDHOOD

Season and region of birth linked to heightened childhood coeliac disease risk

Circulating viral infections may explain temporal/geographical associations, say researchers

Circulating viral infections may help explain the temporal and geographical patterns associated with the risk of developing childhood coeliac disease, conclude Swedish researchers in the ***Archives of Disease in Childhood***.

But the role of vitamin D during pregnancy may also have a part to play, they suggest.

They base their findings on a long term study of almost 2 million children up to the age of 15 who had been born in Sweden between 1991 and 2009.

In all, 6569 of these children from 47 hospitals across the country were diagnosed with coeliac disease—a condition in which the small intestine is excessively sensitive to gluten, making it hard to digest food—before the age of 15.

Overall, the risk of diagnosis was around 10% greater among children born in spring (March-May), summer (June-August), and autumn (September-November) than it was among those born in winter (December-February).

But seasonal patterns differed by region. Risk of coeliac disease was highest among those born in the south of the country, where sunlight in spring and summer is intense, than it was among children born in the north of the country, where springs are colder and summers shorter.

Furthermore, children diagnosed before the age of 2 seemed to be at increased risk of the disease if they were born in spring, while those diagnosed after this age were at increased risk if they were born in summer or autumn.

Year of birth was categorised into three periods to see if there were any differences in trends: 1991-1996, when there was an epidemic of new cases; 1997-2002 which followed the epidemic; and 2003-2009 when the epidemic had abated.

This showed that children born in 1991-6 were at increased risk of being diagnosed with celiac disease if they were born during the spring, while children born in 1997-2002 were at increased risk if born during the summer and autumn. Those born in 2003-09 were at increased risk if born in the autumn.

Risk of coeliac disease was consistently higher among girls than it was among boys for all time periods and seasons.

This is an observational study so no firm conclusions can be drawn about cause and effect, added to which the study authors were unable to glean any information on potentially influential factors, such as infections and vitamin D status.

But they nevertheless speculate about possible explanations for their findings.

“One hypothesis for increased [coeliac disease] risk and spring/summer birth is that those infants are more likely to be weaned and introduced to gluten during autumn/winter, a time characterised by exposure to seasonal viral infections,” they write.

Viral infections alter intestinal bacteria and increase the permeability of cells lining the gut, which could prompt the development of coeliac disease, they suggest.

In Sweden, it is well known that the yearly epidemics of respiratory syncytial virus, rotavirus, and flu start in the south of the country and move northwards, which might also explain the associations seen, they add.

Low levels of vitamin D have also been linked to immune related diseases, such as multiple sclerosis, inflammatory bowel disease, and type 1 diabetes, although every child in Sweden is given state funded vitamin D supplements from 1 week of age up to the age of 2 years.

“A remaining possible link to sunlight and vitamin D is that pregnant women who give birth in spring have the lowest levels of vitamin D during late gestation when important programming and development of the fetal immune system takes place,” they suggest.
