perceived in the implementation of successful mitigation strategies. Data was later utilized for descriptive analysis.

The survey was sent to 317 participants, obtaining 71 answers (22.3% response rate). 23% of the respondents where pediatric residents. 84.5% consider that managing pain related to MPP is relevant and must be addressed in every patient. The procedures perceived as most painful (scale from 1 to 10) were arterial punctures (median 9), followed by lumbar punctures and venous punctures (median 7 both). The entire sample declared knowing at least one measure to reduce pain related to MPP, where the most common were: distraction (84.5%), non-nutritious suctioning (78.9%) and topical creams (76%). Still, 15.5% of respondents routinely do not use any measure. 40% declare that during their training they were taught that pain related to MPP should always be managed in a multimodal way, existing effective measures available. 94.4% of respondents believe that there are consequences regarding this type of pain; yet, half of the respondents agree that consequences are minimal and last only for a short period of time. The main barriers against implementation identified are a lack of knowledge of existing available measures (78.9%) and a belief that these require additional time (60.6%).

There is concern among respondents regarding the need for adequate management of this type of pain. In spite of this, a large proportion of participants do not routinely use any measure. This might be explained by an underestimation of the important consequences of this type of pain. The low response rate obtained is one of the main limitations of the study. The findings of this survey could assist in planning better and more effective strategies to support the use of effective measures to reduce pain related to MPP among pediatricians.

X-ray of left shoulder was reported as indicative of possible periosteal elevation of left mid-shaft humerus with a recommendation to consider further imaging.

On second day of admission, patient had low grade pyrexia prompting septic screen. On further imaging, MRI shoulder was performed revealing changes suggestive of osteomyelitis.

His initial inflammatory markers were normal. Diagnosis of osteomyelitis was confirmed based on temperature spikes, MRI finding and clinical improvement in range of movements in left arm after starting on intravenous antibiotics.

Discussion Considering a diverse spectrum of presentation for child abuse, it can throw diagnostic challenges to any clinician to differentiate between a pathological cause and Non-accidental Injury[3]. We had to consider brachial plexus injury, Cerebral palsy as differentials as patient was afebrile initially. It demonstrates how close; range of differentials could be. In past, there are anecdotal example of Neonatal osteomyelitis presenting as Non accidental injury[5].

Prematurity, socio-economic background are independent risk factors contributing to NAI[6]. In one of the American studies, they described NAI doubles risk of mortality by two-fold [7], so one should be very vigilant in dealing with cases of suspected NAI.

Conclusion Our case highlights importance of non-judgemental and neutral approach while dealing with cases of suspected NAI.

Overweight and obesity in children seem to be quite common problem in many countries. The food dominants and preferences are developing in early childhood. Not rationale feeding of infants and their overweight are risk factors for obesity in school age. The goal of study was to assess the physical development and feeding practice of infants based on self reported parental survey.

The anonymous parental survey for parameters of physical development and feeding practice details was done randomly. The parents of 2nd – 3rd year old children were asked to complete special Google-forms. The individual data, overall tables and diagrams were obtained on-line.

Totally 168 filled questionnaires were processed. The data for body weight in the age of 1 year (z-score) shown that 22.6% children had weight > +2σ; 1.8% children had weight > +3σ. For body length it was revealed that 8.9% children had parameter > +3σ. The weight/length indicator for 8.9% children was > +2σ; for 3.0% children > +3σ. The natural feeding since birth was started for 88.1% of children; until 6 months 61.9% of children received breast milk, until 12 months – 54.8%. From those children who received breast milk 35.1% were given also a water during first months. The practice of scheduled feeding followed in 19.1% families. The first solid food in the age of 4-6 months was administered in 91.6% of children; mostly presented by vegetable pure. Part (49.6%) of children received a meat since the age of 7 months. In the age of 9-12 months feeding of infants was quite diverse. But many parents gave to babies food or drinks...
