Coxsackie Group B Virus Infection and Acute Diarrhoea Occurring among Children in Costa Rica*

WILLIAM PELON, VICTOR M. VILLAREJOS, JOHNG S. RHIM†, and FRED J. PAYNE
From Louisiana State University—International Center for Medical Research and Training, in collaboration with the Ministry of Health of Costa Rica and the University of Costa Rica

Although no evidence has been reported linking infection by members of the Coxsackie Group B viruses with the aetiology of endemic diarrhoea, the results of several virological investigations into sporadic outbreaks of this disease have suggested a causal relation between infection by the Coxsackie Group B viruses and the accompanying diarrhoea syndrome (Heggie, Schultz, Gutekunst, Rosenbaum, and Miller, 1960; Felici, Archetti, Russi, Bellochi, and Marzi, 1961; Guardiola, Figueuera de Gonzalez, Kauder, Muñoz, Lopez, Gadea, and Funkenbusch, 1964; Zakstelskaya, Tyan-Mao, and Feklisova, 1964).

Further evidence supporting the above findings is obtained from an accumulation of clinical data from cases found infected with various Coxsackie B virus types and in which diarrhoea was among the symptoms described (Johnsson, 1954; Ginevri and Felici, 1959; Felici and Gregorig, 1959; Artenstein, Cadigan, and Buescher, 1964; Cramblett, Moffet, Black, Shulenberger, Smith, and Colonna, 1964; Sanyal, Mahdavy, Gabrielson, Vidone, and Browne, 1965).

Presented here are the virological findings and their relation to acute diarrhoea, i.e. with onset of diarrhoea within 24 hours in relation to the time of specimen collection, uncovered in the course of a series of random horizontal surveys conducted in Costa Rica in 12 widely separated communities during an 8-month period from February to September 1963 (Fig. 1).

Diarrhoea was defined as 3 or more loose stools within a 24-hour period, except in the case of infants less than 1 year of age for whom 6 or more loose stools were required.

Material and Methods

Epidemiology. Twelve communities of approximately the same size, i.e. 3000 inhabitants, representative of the different geographic, climatic, ethnic, and socio-economic zones of the country, were studied in horizontal surveys throughout Costa Rica.

Since in a series of pilot surveys diarrhoeal diseases and intestinal infections were found to be most prevalent among children, the population sample was randomly selected from those families which had children under 10 years of age. The method of selection used gave each child in this age-group in the community an equal opportunity to be included in the sample.

Virological and clinical examinations were performed only on this sub-sample of 1811 children under 10 years of age, which comprised the study population.

Specimens for virological examination were submitted by 1584 people (87.5%). A portion of the stool specimen was transferred to a sterile container and kept refrigerated for transport to the virology laboratory on the day of collection. If the locality was remote, the specimens were kept under refrigeration overnight and were sent to the laboratory the next morning by air.

Virology. 20% extracts of collected faeces, prepared in a serum-free medium consisting of 0.5% lacticalbumin hydrolysate in Hanks' balanced salt solution and containing 1000 units of penicillin and 100 μg. each of streptomycin and polymyxin B per ml., were inoculated into cultures of HEP-2 cells, into primary cultures of Rhesus monkey renal (MK) cells, and into newborn (less than 18 hours old) Swiss albino mice (Webster strain), the latter by the technique of Hale and co-workers described elsewhere (Hale, Doraisingham, Kanagaratnam, Leong, and Monteiro, 1959). Suspected agents isolated in the cell cultures were passaged into HEP-2 and MK cells for confirmation and characterization. 20% extracts were prepared from mice found paralysed, moribund, or dead after the first 24 hours following inoculation and were inoculated into newborn mice to confirm virus isolation.

Agents isolated from faecal extracts were identified using the usual tube neutralization procedure versus 100 antibody units of specific rabbit antisera for Coxsackie Group A, Type 9, and the Coxsackie Group B, Polio and ECHO virus types.* Isolates were considered as

Coxsackie Group B Virus Infection and Acute Diarrhoea

Results

Preliminary analyses of virus isolation data employing a tentative system of classification based upon host susceptibility, passage characteristics, and distinctive cytopathology suggested an association between the diarrhoeas encountered in the surveys of the various communities and infections by agents considered as Coxsackie Group B types (Table I). When isolations of such agents from acute diarrhoea (i.e. 24 hours or less between onset and the time of specimen collection) were compared with those from children experiencing no diarrhoea, the differences appeared even more marked. An examination of the data on the basis of diarrhoea rates occurring among infants infected and non-infected with agents considered as Coxsackie B types revealed that the frequency of diarrhoea among the infected infants was almost twice that observed among the non-

infected (Table II). This difference is statistically significant, p < 0.01.

On the basis of these preliminary indications, an analysis of virus isolations from acute and more prolonged cases of diarrhoea was undertaken, with the crude tentative classification of the isolates confirmed or amended by serological procedures.

The rates of virus isolation from faecal specimens collected from acute and more prolonged cases of diarrhoea occurring among children less than 10 years of age in Costa Rica are shown in Table III. It can be seen that the over-all rate of virus excretion as detected with the 3 host systems employed was quite high, averaging approximately 75% for the 3 categories investigated. The maximum rate of 83% was noted from faecal specimens of children whose onset of diarrhoea was 24 hours or less before the collection of specimen material. The distribution of the identified Coxsackie B types from these cases among the different communities under study is shown in Fig. 2.

If the over-all infection rates by the Coxsackie Group B types are examined, the maximum isolation rate (47%) for these agents was also obtained from children with acute diarrhoeas, with types 4 and 5 predominating. This rate rapidly declined to an average frequency of 9% when diarrhoeas of 48 and 72-96 hours' duration before specimen collection were considered. In contrast, the isolation of the non-Coxsackie Group B virus types, i.e. members of the ECHO and Coxsackie A virus groups, from cases of acute diarrhoeas occurred at a somewhat lower rate (25%), but gradually increased to an average of 45% from diarrhoeas of 48- and 72-96 hours' duration. These frequencies of virus isolation are graphically presented in Fig. 3. 14 (15%) of the isolates have not yet been identified.

**Discussion**

In Costa Rica, diarrhoeas in infants and children are of common occurrence, with an anticipated average of 10 episodes per year per child of less than 2 years of age. As a result, such illnesses are often not treated during the acute phases. Therapy, if employed, is limited to home remedies or medications purchased from local pharmacies. A review of the records of children who have attended outpatient clinics or who have been hospitalized in San José because of diarrhoea has indicated that the majority experienced diarrhoea for periods of 48 hours or longer before therapy was sought. It is not unreasonable to assume that similar situations exist elsewhere in areas where diarrhoeas are a common problem.

It should be emphasized that the 36 acute cases of diarrhoea shown in Fig. 1 were not deliberately selected for study, but were uncovered by chance during a random series of horizontal surveys conducted in 12 Costa Rican communities. Although acute diarrhoeas, as defined, were observed in 11 of the 12 survey localities, subjects actually experiencing an episode of diarrhoea during the time of interview were encountered in all the villages under investigation.

The data presented in Table III suggest a possible aetiological relation between infection by the Coxsackie Group B virus types and a proportion

of the endemic diarrhoeas occurring among the younger children in Costa Rica. It is of interest to note that the isolations of the Coxsackie B virus types from cases of acute diarrhoea were not limited to a particular community, which would be suggestive of a localized outbreak similar to that observed elsewhere (Felici et al., 1961). As seen in Fig. 2, these were broadly distributed, being obtained from specimens collected from 8 of the 11 communities where this syndrome, as defined, was observed.

Although 15% of the isolates have not yet been identified, it is doubtful whether such information would alter the existing data significantly. This is illustrated in Fig. 4 and 5. If it is assumed that the unidentified agents isolated in both cell cultures and newborn mice were members of the Coxsackie B group and those isolated in cell cultures only were non-Coxsackie Group B viruses (Fig. 4), some differences in the frequencies of isolation would be observed when compared with the data presented in Fig. 3. Although an increase in the isolation rates of the Coxsackie Group B viruses would occur (Fig. 4), the slopes of the curves for virus isolation from diarrhoeas of 24 and 48 hours’ duration are identical when both figures are compared. Non-Coxsackie B agents (Fig. 4) also show an increase in the frequency of isolation from the 72-96 hour diarrhoeas. In contrast, if it is assumed that all of the unidentified
agents were ultimately identified as non-Coxsackie B types (Fig. 5), such findings would reduce differences in the rates of isolation of the Coxsackie B and non-Coxsackie B types from diarrhoeas of 24 hours' duration, but would also tend to broaden the differences in the frequencies of isolation between the two groups from diarrhoeas of 48 and 72-96 hours' duration.

Although virological investigations of endemic diarrhoeas are not unique, the data presented thus far place strong emphasis upon the necessity of collecting specimen material from cases of diarrhoea during the acute phases of the disease, a procedure recognized and recommended for the recovery of most agents (Lennette, 1964).

Currently, it is not possible to project our findings in Costa Rica to other areas where endemic diarrhoeas prevail. Nevertheless, it is of interest to note that where virological investigations of diarrhoeas occurring in endemic areas have been carried out, the study population usually consisted of subjects who either were attending out-patient clinics or were hospitalized because of this disease (Guardiola-Rotger et al., 1964; Reitano and Dardanoni, 1961; Young, Lindberg, Ortiz, Jahiel, Sochard, and Hemphill, 1962; Malherbe and Roux, 1963; Ramos-Alvarez and Olarte, 1964; Nuñez-Montiel, Herold, Castillo, Angelillo, Irazábal, Gómez Malaret, and Vitelli-Flores, 1965).

In such studies, ratios of the non-Coxsackie Group B types as compared with the frequencies of isolation of Coxsackie Group B virus types from cases of diarrhoea (NCB : CB ratio) ranged from 2 : 1 to 62 : 1, with 5 of the 6 investigations reporting findings having ratios of 5 : 1 or greater. If the data from Costa Rica were analysed in a similar manner, the NCB : CB ratios ranged from 0·5 : 1 from acute diarrhoeas to 14 : 1 and 3 : 1 from diarrhoeas of 48 and 72-96 hours' duration, respectively.

Further support of the Costa Rican findings is obtained from one of the investigations described above (Guardiola-Rotger et al., 1964). Even though an over-all virus isolation rate of only 14% was obtained from cases of diarrhoea, 57% of the agents isolated were shown to be members of the Coxsackie B group, with 8 of the 9 Coxsackie B isolates classified as type 4.

In view of the data obtained in Costa Rica, speculation now arises as to what the findings would have been in those investigations of endemic diarrhoeas mentioned above, if diarrhoeas during their acute phase (i.e. 24 hours or less between onset and the time that specimen material was collected) had been investigated.

Summary

Virological investigation of acute diarrhoeas (24 hours or less between onset and time of specimen)
Coxsackie Group B Virus Infection and Acute Diarrhoea

We gratefully acknowledge the untiring support of the personnel of the Ministry of Health of Costa Rica, and the University of Costa Rica. From the Ministry of Health we particularly want to thank Dr. Max Terán Valls and Dr. Oscar Tristán, the Ministers of Health during the study, Dr. Rodrigo Jiménez Monge, Director of the Department of Epidemiology, and Dr. Arturo Romero, Director of the Department of Health Units. From the University of Costa Rica we should like to thank Dr. Mario Miranda Gutiérrez, Dean of the School of Medicine, Dr. Fernando Montero Gei, Dean of the School of Microbiology, and Dr. José Amador Guevara, Head of the Department of Preventive Medicine.
