SUMMARY  An 8-month-old boy with persistent watery diarrhoea and failure to thrive developed abdominal distension, hypokalaemia, and flushing of the face and trunk. A high concentration of vasoactive intestinal peptide-like immunoreactivity was found in the serum. Soon after resection of a suprarenal mass, the serum level of vasoactive intestinal peptide became normal and the diarrhoea stopped. Histologically the tumour was a ganglioneuroblastoma: the cells showed fluorescence by the indirect immunofluorescence technique with anti-vasoactive intestinal peptide serum. Electron microscopical examination showed abundant secretory granules in the tumour cells. Reports of chronic watery diarrhoea in children due to neural crest tumours are reviewed, with particular respect to the clinical features of the syndrome.

It is well known that a neural crest tumour should be considered in seeking the cause of unexplained chronic diarrhoea.1 In the past, catecholamines and related metabolites had been thought to be the causative agents of such diarrhoea,3–5 but this idea has now been abandoned.1, 4–6 Recently it was proposed that vasoactive intestinal peptide (VIP) might be the cause of the watery diarrhoea syndrome6–7 and that an increased plasma VIP concentration was diagnostic.6–9 In Bloom’s series,10 7 of 39 patients with high concentrations of plasma VIP were found to have either a ganglioneuroma or a ganglioneuroblastoma. Only 5 children with the watery diarrhoea syndrome and increased VIP concentrations in the plasma or tumour tissue extracts11–15 have been reported. In one of them the location of the VIP-producing tumour was obscure,13 but each of the other 4 children had a ganglioneuroma or a ganglioneuroblastoma.

In 1975, we reported a typical case of the watery diarrhoea syndrome due to a ganglioneuroblastoma, but we did not measure the plasma VIP.16 We now report another such case, and suggest that the high level of serum VIP is the cause of the watery diarrhoea.

We also review reports of chronic diarrhoea in children with neural crest tumours, and discuss the clinical features useful in arriving at an early diagnosis of VIP-producing tumours.

Case report

An 8-month-old boy presented with protracted diarrhoea, abdominal distension, and failure to

Fig. 1 The inferior vena cava is compressed by the tumour.
thrive. He had been born after 35 weeks' gestation and had weighed 2.5 kg at birth. At 4 months his mother noticed abdominal distension. At 7 months watery diarrhoea began, and with abdominal distension and weight loss now severe, he was admitted to a local hospital. The diarrhoea persisted even during intravenous feeding. Hypokalaemia (2.6 mmol/l) and hyponatraemia (126 mmol/l) were noted. Lactose-free or soy feeds were ineffective. After 16 days he was transferred to our hospital.

On admission, he weighed 5.3 kg and measured 64 cm. He was poorly nourished, with moderate dehydration. Abdominal distension was pronounced and bowel sounds diminished. There was no palpable abdominal mass. His bowel movements, 5 to 8 times a day, were watery and brown and were not mixed with blood, mucus, or undigested food. He showed temporary flushing of the face and trunk, but blood pressure was normal (110/70 mmHg).

Total parenteral nutrition for one week did not reduce the diarrhoea. Intravenous potassium supplements (8–10 mmol/kg per day) were necessary to maintain normal serum potassium. Haematological values and erythrocyte sedimentation rate were normal. Serum analyses: sodium 134 mmol/l, potassium 2.5 mmol/l, chloride 105 mmol/l, glucose 5.3 mmol/l (96 mg/100 ml), plasma urea 4 mg/100 ml (1.43 mmol/l), calcium 9.6 mg/100 ml (2.4 mmol/l), albumin 5.3 g/100 ml (53 g/l), total protein 7.6 g/100 ml (76 g/l). Serum concentrations of bilirubin, aspartate transaminase, and alanine transaminase were normal: lactic dehydrogenase was 774 units (normal, <500 units). No pathogenic bacteria were cultured from the faeces. A screening test for urinary vanillyl mandelic acid (VMA) was negative. Plain x-ray films of the abdomen showed amorphous calcifications in the right upper quadrant. A urogram located these calcifications in the right suprarenal area. Abdominal angiographs showed the existence of a suprarenal mass with moderate vascularity. The inferior vena cava was compressed by the tumour (Fig. 1).

Fig. 2 Pure ganglionic cell area of well-differentiated ganglioneuroblastoma showing a collection of large ganglion cells and Schwann's sheath proliferation.
Barium enema showed generalised dilatation of the colon. The serum VIP concentration was high (608 pg/ml).

On the 10th day after admission, laparotomy was performed and a 6.5 × 3.5 × 3.0 cm (40 g) encapsulated solid tumour was removed completely. No abdominal metastasis was found. Soon after surgery the watery diarrhoea stopped and subsequently the weight gradually increased. Our patient is now 2 years old and progressing well.

Methods

Twenty-four hour urine specimens were collected and stored at -20°C. Urinary VMA and homovanillic acid (HVA) were measured by the methods of Pisano et al.17 and Ruthven and Sandler.18 Urinary catecholamines were measured by the method of Seki et al.,19 using high-speed liquid chromatography. Fasting serum immunoreactive VIP was assayed with antisera (R-502) to synthetic porcine VIP.20

Fluorescence staining for immunohistological detection of VIP was performed by the indirect immunofluorescence technique with rabbit antiserum against synthetic porcine VIP as the first antibody, and fluorescein isothiocyanate-labelled

goat anti-rabbit IgG antiserum as the second antibody.

Results

Twenty-four hour urinary excretion of catecholamines and their metabolites is shown in Table 1. The preoperative levels of dopamine and HVA were moderately high, but these levels became normal after operation.

The serum immunoreactive VIP level (608 pg/ml) was high before operation. One hour after resection of the tumour, the VIP level had already fallen to 130 pg/ml (normal range for our laboratory 200 pg/ml or less\(^\text{20}\)), and the values 2 and 3 months after operation were both normal.

Histologically the tumour was a typical ganglioneuroblastoma. It consisted mainly of large ganglion-like cells with prominent nuclei and nucleoli. Some cells appeared to be poorly differentiated. They were dispersed in a loose stroma forming a fibrillary cobweb-like network (Fig. 2).

Fig. 4a  Indirect immunofluorescence with highly specific rabbit antiserum against synthetic porcine VIP. Note that the specific fluorescence for VIP was observed diffusely in the cytoplasm of tumour cells. (× 400).

Fig. 4b  Haematoxylin-eosin staining of section adjacent to Fig. 4a. The VIP-positive tumour cells have abundant acidophilic cytoplasm and a chromatin-rich nucleus. (× 400).
Electron microscopical examination showed that most ganglionic tumour cells had a nucleus with a prominent nucleolus. The cells had abundant cytoplasm containing numerous organelles and many round or oval granules (Fig. 3). Among the large tumour cells there were many neurites with abundant neurotubules and various numbers of secretory granules and vesicles. In some areas of the plasma membrane of the neurites there were synaphe-like structures.

Immunohistochemical studies with rabbit antiserum against synthetic porcine VIP showed specific fluorescence for VIP diffusely distributed in the cytoplasm of only certain tumour cells, which were clustered in restricted areas—that is, the VIP-positive tumour cells were not evenly dispersed. Histologically, these VIP-positive tumour cells had abundant, rather acidophilic cytoplasm, and much chromatin in the nucleus (Figs 4a, b).

**Discussion**

In the past, measurement of urinary catecholamines or metabolites has been recommended as the most useful aid in diagnosis of neural crest tumour.21 In many patients presenting with diarrhoea increased excretion of urinary catecholamines is present, but it is difficult to explain the diarrhoea simply as an effect of these substances.3–5 14 because not all patients who have such tumours and secrete large amounts of catecholamines do have diarrhoea. Again, patients with pheochromocytoma secrete large quantities of catecholamines, but rarely have diarrhoea as a main symptom.3

Recently, an increase in the concentration of VIP was noted in the plasma or tumour tissue of patients with the watery diarrhoea syndrome6–7 10 and it was proposed that VIP was the cause of this syndrome and that its measurement was of diagnostic value.8–10

VIP is a biologically-active polypeptide of 28 amino-acid residues,28 first isolated from hog small intestine by Said and Mutt29–31 in 1970. Of the various biological actions of VIP, the following seem to be especially important in the watery diarrhoea syndrome: (1) stimulation of adenylate cyclase activity and secretion of intestinal mucosa,25–26 (2) both splanchnic and systemic vasodilatation,23–24 and (3) inhibition of both pentagastrin- and histamine-stimulated gastric acid secretion.27–28 These effects could explain the clinical symptoms of this syndrome—such as severe refractory watery diarrhoea, hypokalaemia, flushing attacks, and achlorhydria. Besides these actions, VIP is reported to induce hyperglycaemia29 and hypercalcaemia.30 A VIP-producing tumour with the same features as our case was recently reported by Modlin et al.31

Recently, Modlin et al.9 showed that continuous infusion of VIP caused severe diarrhoea, flushing, and hypokalaemia in pigs, and that the resulting increase in the concentration of VIP serum was comparable with that found in humans with the watery diarrhoea-hypokalaemia-achlorhydria (WDHA) syndrome.

VIP may be the cause of many cases of watery diarrhoea, but not of all cases32 since some may be due to pancreatic polypeptide.53

With regard to early diagnosis, there are reports of only 5 children with this syndrome in whom the plasma or tumour VIP was measured. But the literature provides much other information on cases where diarrhoea in infants and children has been associated with a neurogenic tumour, which we have summarised in Table 2. It seems that the following clinical features are important for diagnosis. (1) Age: although the syndrome is found in persons of all ages, but is more common in infants and young children (Table 2). In adults WDHA syndrome is often seen to be due to a pancreatic tumour, whereas in children it is often due to a ganglioneuroblastoma.34 (2) Chronic watery diarrhoea, which is refractory to diet and to total parenteral nutrition: bowel movements are not always frequent, and some patients have large fluid stools only once or twice a day. (3) Hypokalaemia: of 19 cases with records of serum potassium, 14 had hypokalaemia (Table 2). The hypokalaemia is not necessarily continuous, but occurs in repeated severe episodes (1·4–3·7 mmol/l in Table 2). Supplementation with large quantities of potassium may be necessary.13–14 (4) Abdominal distension and colonic dilatation: distension is not necessarily due to hypokalaemia, but may rather be an effect of VIP. (5) Transient response to corticosteroids: there are few reports of administration of corticosteroids to patients with this syndrome, but in all those reported (6 reports in Table 2) transient improvement of the symptoms was noted.3–4 10 15–16 35 The reason for the effects is unknown, but the effect of corticosteroid could be a diagnostic aid. (6) Hypoglycaemia and inhibition of gastric acid secretion: these symptoms have been reported frequently in adults with the WDHA syndrome, but only occasionally in children with this syndrome.14 (7) Flushing: the frequency of the appearance of flushing or rash is not high, and indeed only 7 are shown in Table 2. However, flushing appears only transiently, and so is easily overlooked. In experiments on pigs by Modlin et al.,9 flushing was noted in all. (8) Urinary excretion of catecholamines and their metabolites: catecholamines are not causative agents of the diarrhoea, and moreover they are not always increased in this syndrome. 13 of 21 cases in

GN = ganglioneuroma, NB = neuroblastoma, GNB = ganglioneuroblastoma.
Table 2 showed increased urinary excretion of VMA, but 8 cases showed little or none. However, neurogenic tumours are often associated with abnormal excretion of catecholamines, and so it is important to measure urinary VMA. Measurement also of HVA and catecholamines (dopamine, noradrenaline, and adrenaline as well as VMA) would be somewhat more effective. (9) Measurement of plasma VIP: measurement of VIP in carefully preserved frozen plasma may prove to be a simple and reliable test for diagnosis of many cases of this syndrome. Considerable care is necessary during specimen collection and assay. VIP is rapidly destroyed by proteolytic enzymes because it has two basic amino-acid sequences that are particularly susceptible to trypsin-like enzymes. Blood should therefore be taken into a proteolytic enzyme inhibitor (aprotinin, 1000 kallikrein inhibitor units/ml blood) and then rapidly centrifuged and the plasma should be frozen at −20°C within 15 minutes of venepuncture. (10) Detection of tumours: as seen in Table 2, the adrenal and neighbouring regions are the most common sites for tumours, followed by the mediastinum, so that pyelography and chest X-rays are necessary; these tumours frequently show calcification. Other techniques—such as computerised tomography scanning and angiography—may be indicated. (11) Other symptoms: profuse sweating (5 cases in Table 2) and waddling gait (2 cases in Table 2) are sometimes present.
