Liver damage in a neonate with alpha-1-antitrypsin deficiency due to phenotype PiZ null (Z−)

JOHN BURN, DAVID DUNGER, AND BRIAN LAKE

MRC Clinical Genetics Unit, Institute of Child Health and The Hospital for Sick Children, London

SUMMARY An infant with neonatal liver damage had α-1-antitrypsin deficiency, having inherited the Z allele from the father and the rare null allele from the mother. This indicates that while a lack of serum antiprotease predisposes to early liver disease, homozygosity for the Z allele is not essential.

Alpha-1-antitrypsin represents the major serum protease inhibitor and can be quantified on this basis. The use of electrophoresis and isoelectric focusing has helped to identify at least 28 allelic variants, 4 of which are associated with low levels of clinical significance; these are labelled Z, S, null, and M (malt). in the Z (protease inhibitor) classification. There is a complete lack of α-1-antitrypsin on the rare occasions that a homozygote for the null allele is identified.1–3 This allele produces no electrophoretic band; the heterozygous state can be deduced only by quantification and electrophoresis of parental blood.

The association of liver disease with α-1-antitrypsin deficiency has been known since 1969, nearly all cases being presumed ZZ homozygotes. The Piz null (Z−) heterozygote is rare. Sveger4 found 2 Pi Z− neonates among 200 000 screened in Sweden, one of whom was normal; the other had slightly abnormal liver function tests. We could find no previous report of severe liver damage in a child with the Z− phenotype. We report one such case.

Case report

A girl was born weighing 2.08 kg at 37 weeks' gestation, by caesarean section, performed because of cephalopelvic disproportion. She was the first child of unrelated parents, the mother having had 2 normal children by a previous marriage. Polyhydramnios was noted at delivery; the placenta was oedematous and weighed 750 g.

The patient required intubation at birth and regular respirations were not established until 7 minutes had elapsed. During the first 24 hours generalised abdominal distension and hepatosplenomegaly were noted. Her indirect bilirubin, on day 3, was 371 μmol/l (21.8 mg/100 ml) with a normal haemoglobin level, and one exchange transfusion was performed. A top-up transfusion was required on day 11. She failed to thrive and was referred for investigation at 8 weeks.
Examination showed a small, wasted child with a functional systolic murmur. The abdomen was distended and tympanic, with a liver edge 3 cm below, and a spleen tip palpable 3–4 cm below, the costal margin. Examination was otherwise normal. The haemoglobin concentration was 10.6 g/l, with a white cell count of 21.6 × 109/l with 49% lymphocytes, total bilirubin of 48 μmol/l (2.8 mg/100 ml) (direct 26 μmol/l (1.5 mg/100 ml)), total protein 55 g/l, albumin 31 g/l, ALT 1266 IU/l, AST 123 IU/l, 5' nucleotidase 44 IU/l, and alphafetoprotein of 430 μg/l. The bone age was 32-35 weeks but skeletal survey was otherwise normal. Ultrasound examination confirmed liver and splenic enlargement but the kidneys and portal veins were normal. The cx-1 globulin band was absent on plasma protein electrophoresis. The quantitative oc-1-antitrypsin level was 0.4 g/l (40 mg/100 ml); in the mother it was 0.8 g/l (80 mg/100 ml) and in the father 1.2 g/l (120 mg/100 ml). Further studies showed the Z pattern in the patient, M pattern in the mother, and MZ in the father. This indicated that the mother was a heterozygote for the M and null alleles and that she had passed on the null allele to her daughter who by inference must have the Z− phenotype.

A needle liver biopsy at age 10 weeks 5 days showed preservation of the lobular architecture with prominent portal areas containing increased connective tissue. There was an accumulation of fat and diastase resistant-periodic acid-Schiff (PAS) positive globules in hepatocytes predominantly in the perportal regions, although PAS-positive droplets were found throughout the lobules (Figure). Bile pigment was present mainly within hepatocytes particularly in the centrilobular regions. Electron microscopical examination showed an accumulation of an amorphous substance within distended endoplasmic reticulum of hepatocytes.

The following investigations were normal: plasma electrolytes, calcium, phosphate, copper and zinc, thyroid function tests, urinary mucopolysaccharide, organic acid and amino-acid screens. Vacuolated lymphocytes were not detected and serology—including a TORCHES* screen, Paul-Bunnell, and Australia antigen—was negative. Chest x-ray films, barium meal, barium enema, sweat test, and electrocardiograms were normal.

Discussion

We report a child with α-1-antitrypsin deficiency associated with the Z− phenotype who suffered

- Toxoplasma, rubella, cytomegalovirus, herpes, echo, syphilis.
neonatal hepatitis of prenatal onset, and has persisting hepatosplenomegaly. Neonatal hepatitis is associated with \( \alpha \)-1-antitrypsin deficiency in 10 to 20\% of cases, the majority being homozygous for the Z allele. The Z\(^\gamma \) phenotype can be distinguished only by examination of the parental phenotypes.

The occurrence of neonatal hepatitis in our patient suggests that while low levels of plasma antiprotease activity are a factor in the aetiology of liver damage, such damage can occur without the presence of two Z alleles. Many individuals deficient in antiprotease activity have normal liver function however, so one or more other factors must be involved.

One may speculate on the nature of the second factor. It is not the PAS-positive deposits. Their presence and distribution show no correlation with liver damage. The limited family data suggest that ZZ individuals are at much greater risk of liver damage if a ZZ sibling has had liver disease, but the observation of monozygotic twins with the ZZ phenotype being discordant for liver disease is against the second factor being a separate gene defect. Attempts to identify infective or other environmental agents have not been successful. A further possibility is that low levels of \( \alpha \)-1-antitrypsin predispose, in some way, to immune damage to the fetal or neonatal liver. This is supported by the observation that lymphocytes from individuals with hepatitis and antiprotease deficiency are cytotoxic for isolated rabbit hepatocytes. As there is evidence that maternal lymphocytes enter the fetal circulation, these could become similarly sensitised; this would provide an explanation for the increased incidence of liver damage in \( \alpha \)-1-antitrypsin-deficient individuals whose previous sibling was affected.

We thank Dr D W Hide and Professor Otto Wolff for permission to report this case, Miss P Goffron for preparing the manuscript, and Dr A Milford Ward and the staff of the Supraregional Specific Protein Reference Unit, for performing the \( \alpha \)-1-antitrypsin electrophoresis and quantitation.

Oral solutions for gastroenteritis—optimal glucose concentration

B KJELLMAN AND E RONGE

Department of Paediatrics, Karnsjukhuset, Sweden

**Summary** About half of all infants and toddlers with infectious diarrhoea of probable virus aetiology and treated with an oral rehydration solution containing 4-6% glucose had faecal glucose ≥ 0.3%. In most of them the faecal concentration of glucose was higher than 0-50%. From the physiological point of view, it seems wise to decrease the glucose concentration substantially from that so often recommended for the treatment of diarrhoea in developed countries.

We thank Dr D W Hide and Professor Otto Wolff for permission to report this case, Miss P Goffron for preparing the manuscript, and Dr A Milford Ward and the staff of the Supraregional Specific Protein Reference Unit, for performing the \( \alpha \)-1-antitrypsin electrophoresis and quantitation.
