SUMMARY Human coronavirus were found by enzyme linked immunosorbent assay in upper respiratory tract secretions taken during 30% of 108 acute respiratory infections experienced by 30 children under age 6 years with recurrent respiratory infections (index group), and during 29% of 51 acute infections experienced by their siblings. Lower respiratory tract infection—predominantly wheezy bronchitis—occurred in 30% of the index children's positive infections but in none of their siblings' infections. Reinfections were common. Two peaks of infection were seen each year in the late autumn/early winter and in the early summer.

Many human coronavirus (HCV) isolates have been reported to cause upper respiratory tract infections in both children and adults. These isolates all fall into 1 of 2 distinct antigenic groups, named after the prototype strains, HCV 229E and HCV OC43. Coronavirus cause wheezing in young asthmatic children but only rarely cause wheezing in normal children. The clinical features of HCV OC43 infection in childhood have been well described, but not those of HCV 229E.

Previous epidemiological studies on HCV respiratory infections in children have been based on serological evidence of infection because the difficulties in growing HCVs in conventional tissue and organ cultures make direct isolation difficult. The disadvantage of serological studies is that they need at least 2 serum samples taken several weeks or more apart. We have recently developed an enzyme linked immunosorbent assay (ELISA) for detecting HCV antigens in nasal secretions from children with respiratory infections. This assay needs only a single sample of a nasal secretion taken at the peak of infection. We describe a prospective study of acute respiratory infections in children and the epidemiological features of infection with HCV 229E and HCV OC43 group viruses found in samples of nasal secretions by ELISA.

Patients and methods

Thirty children aged 6 months to 6 years presenting consecutively to the paediatric department of this hospital with recurrent upper or lower respiratory tract infections were admitted to a prospective study. The index group children were reported by their parents as having had at least 10 infections in the previous year and all had an unaffected sibling in the same age range who acted as control. Each sibling pair was followed prospectively for 1 year from admission to the study, which was carried out from October 1979 to February 1981. These children have been described in detail.

Index and control children were visited at home by DI during each acute respiratory illness. A clinical diagnosis, made according to the criteria of Court, was recorded along with records of signs and symptoms, and the parents kept a record card of subsequent progress. Because this study was done on patients at home and not in hospital, pneumonia was generally diagnosed on the clinical grounds of diminished air entry and crepitations, as used in studies of acute respiratory illness in general practice. Nose and throat swabs were taken with sterile wool swabs and broken into viral transport medium containing penicillin, streptomycin, and amphotericin. A neonatal mucus extractor and mucus trap was used to take a nasopharyngeal aspirate, to which was added 2 ml of viral transport medium. Specimens were taken to the laboratory frozen on solid carbon dioxide and stored at -70°C until inoculated onto cell culture. Organ cultures were not used.

Antisera to HCV 229E and CV Paris, a virus antigenically closely related to HCV OC43, were prepared in New Zealand White rabbits from sucrose gradient purified virus preparations. These antisera were then used in ELISAs to detect HCV 229E and HCV OC43 group viruses in the nasal secretions of the children. The method used and the criteria for identifying which specimens contained HCV antigens have been described.

One hundred and fifty nine samples were tested—
The respiratory signs and symptoms of preschool children with HCV infections are shown in Table 2 and the clinical diagnoses made in association with each infection in Table 3. The diagnoses in dual infections (HCV and another virus) have been added in parentheses to show that these do not alter materially our results or conclusions.

The index children had lower respiratory tract infections, predominantly wheezy bronchitis, during 10 (30%) of their HCV infections, whereas HCV infections in the control children were of the upper respiratory tract only. We have seen a similar clinical pattern with other respiratory virus infections: the index children were more likely than their siblings to wheeze during respiratory virus infections and this was not due solely to atopy.17

Six children had reinfections with HCVs after disappearance of the antigen in intervening specimens and 1 of these children had 2 reinfections. In 4 children the antigen was present in consecutive

Numbers in parentheses indicate dual infections with HCV and another virus.
specimens taken from separate illnesses 13 to 29 days apart, and 4 further children had antigen in consecutive specimens 2 or 3 months apart (65 to 105 days). This may mean either reinfection or that they are carriers of HCVs.

Three peaks of HCV infection were observed during the 18 months of the study (Figure): 2 in the late autumn/early winter of 1979 and 1980 and 1 in the early summer of 1980. No HCV infections were found in the months between these peaks.

Discussion

We have shown that coronaviruses were found in 30% of acute respiratory tract infections of children under 6 years between October 1979 and February 1980. This may be an over estimate as specimens from which other respiratory viruses had been isolated were less likely to be used (see above). Similar results were obtained by Monto and Lim who found that children under 5 years had a 29% infection rate with HCV OC43. These studies cannot be readily compared, however, as we found HCV infections by measuring antigen in nasal secretions, whereas Monto and Lim detected HCV infections by serological techniques.

We also confirmed McIntosh's suggestion that coronaviruses may be important precipitants of asthmatic attacks in young asthmatic children. Our index children had lower respiratory tract infections, predominantly wheezy bronchitis, during 30% of HCV infections. We showed that these children were more likely than their siblings to wheeze during all respiratory virus infections but that this was not due solely to atopy, and we suggested that the index children were less efficient at eradicating respiratory viruses from their upper respiratory tract.

One problem in the interpretation of our results is uncertainty as to how often HCV occurred in conjunction with other respiratory pathogens that we could not detect. This is a common problem in epidemiological studies of acute respiratory infections, in which even the most rigorous search for respiratory viruses may yield a detection rate of only 20 to 30%. We isolated respiratory viruses—excluding coronaviruses—from 38% of all acute respiratory infections, however, and believe that undetected pathogens would not have altered materially our epidemiological conclusions.

Reinfections with HCVs were common. Furthermore, we found HCVs in secretions taken from consecutive acute infections more than 3 months apart. This may show that the virus is carried in the upper respiratory tract: it is known that adenoviruses are carried for many months. Three of the specimens tested were positive for both HCV 229E and HCV OC43 group viruses: this could be caused by simultaneous HCV infections or by a single infection with an HCV bearing common antigens.

Infections caused by HCV 229E and HCV OC43 group viruses follow a complex pattern, although they usually occur in 2 to 3 year cycles. In general, high infection rates in any particular year are caused by either HCV 229E or HCV OC43 group viruses and there are sporadic infections only with HCVs belonging to the other group. During our study there was a high rate of infection caused by HCV 229E group viruses with only minor activity of the HCV OC43 group virus.

Studies in the USA have determined the periods of HCV infection by measuring the increase in antibodies to HCVs in selected populations. These results show that epidemics occur during the winter and early spring, with the peak period varying by several months. Other periods of high infection have, however, been observed and during these periods a recent study in the United Kingdom showed that HCV infections in adults occurred throughout the year with major peaks of infection during the summer as well as the winter. Our study shows that HCV infections of children also occur in both summer and winter months.

We acknowledge the generous financial assistance of the Medical Research Council and the Nuffield Foundation. We thank Dr D A J Tyrrell for advice and encouragement.
