SUMMARY Abdominal ultrasound imaging was performed in 50 children. Thirty nine were proved to have cystic fibrosis while 11 had respiratory infections and thus acted as controls. The pancreas was abnormal in 75% of cystic fibrosis patients aged under 5 years and in 95% over 5 years. In cystic fibrosis patients over 5 years old who had malabsorption, the pancreas was abnormal in 100%. Abnormalities of the liver parenchyma were found in 23%, of the gallbladder in 24%, and splenomegaly in 8% of the cystic fibrosis patients.

Cystic fibrosis is the most common recessive inherited disease in Caucasians with an incidence of approximately 1:2500, and one in 20 of the population are carriers. In large centres experienced in the management of cystic fibrosis, 80% of patients now live beyond their 20th birthday, largely because of advances in the management of the respiratory complications. Increased survival has resulted in the growing importance of problems related to the dysfunction of the pancreas, liver, and biliary system. Detection of liver involvement in cystic fibrosis is notoriously difficult. Over inflation of the lungs makes radiological and clinical assessment of the liver and splenic size unreliable. Liver function tests do not become abnormal until relatively late in the disease and may not be seriously deranged even in the presence of oesophageal varices. Needle biopsy is of limited value in detecting the focal liver involvement. Ultrasound scanning can be used to detect and, by serial examinations, monitor the progress of liver changes and the signs of portal hypertension. Occasionally the diagnosis of cystic fibrosis is in doubt and the ultrasonic finding of a definitely abnormal pancreas can be helpful in supporting the diagnosis.

Patients

A total of 50 patients were scanned. Eleven were children with chest infections who acted as controls and 39 had typical cystic fibrosis with abnormal sweat electrolytes by the pilocarpine iontophoresis method. The age range was 1 to 21 years and 12 of the cystic fibrosis patients were under 5 years.

(Table 1). Nineteen of the cystic fibrosis patients were boys and 20 were girls.

Methods

A number of biochemical liver and pancreatic function tests were performed as part of a periodic comprehensive clinical and laboratory assessment of cystic fibrosis patients. Of particular relevance are determinations of serum bilirubin, serum alanine leucine transaminase, alkaline phosphatase, albumin, immunoreactive trypsin, prothrombin time, and the faecal fat output and percentage fat absorption. These results were compared with the ultrasonic findings.

The ultrasound scans were performed in a routine clinical department by a variety of ultrasonographers using a number of commercially produced machines. During the initial phase of the study static 'B' scanners were used, while later on real time scanners became available. The patients were fasted and neither the ultrasonographers nor the two radiologists who interpreted the scans (HCI and CWS) were aware of whether the patient had cystic fibrosis or was a control. The scanning techniques
and criteria for scan interpretation used in our department have recently been described. Echo amplitude analysis was performed on a subjective basis using echo amplitude levels in other non-pathological organs for reference and taking into account other factors such as signal processing artefacts and transducer beam profile characteristics that would affect the recorded echo amplitudes.

The pancreas was considered normal if its echogenicity was approximately the same as the liver parenchyma at the same depth from the skin surface. The liver was first assessed by comparison with the parenchyma of the right kidney so that it could be used as a true reference. The pancreas was classified as abnormal if it was considerably more echogenic than the liver at the same depth, and was subjectively graded into 1 and 2—grade 2 being the more echogenic (Fig. 1). Obvious shrinkage of the pancreas was noted, although absolute measurements were not recorded. Measurements can be unreliable since the shape of the pancreas varies with respiration and often the margins of the shrunken pancreas become indistinct and on ultrasound scan seem to merge with surrounding retroperitoneal fat. The liver was considered normal if it was only slightly more echogenic than the right renal cortex at an equivalent depth. Diffusely or patchily increased echogenicity was considered abnormal (Fig. 2). The appearances of the gallbladder were documented, and the presence or absence of stone or biliary sludge was noted. A subjective assessment of gallbladder size was made, and microgallbladder was diagnosed when obviously very small and shrunken (measurements of less than $3 \times 1$ cm are considered indicative of microgallbladder).

Spleen size was assessed by comparison with the left kidney but portal vein size was not documented because of the reported low sensitivity of calibre measurements in the detection of portal hypertension.

**Results**

The pancreas was normal in nine of the 11 control children and could not be visualised in two. Of 27 patients with cystic fibrosis in whom the pancreas was visualised, it was normal in three (11%) but abnormal in 24 (89%). The pancreas could not be visualised in 12, mainly because of bowel gas which is a particular problem in cystic fibrosis patients (Table 2).

Two of the three patients with normal ultrasonic appearances of the pancreas were young (1-3 and 4-3 years) and it may be that the characteristic pancreatic changes of cystic fibrosis had not pro-

patients had an abnormal serum alkaline phosphatase concentration and four of these had abnormal ultrasonic appearances. Only two of the nine patients with a raised serum alanine leucine transaminase concentration had abnormal ultrasonic findings. The two patients with grade 2 appearances in the liver both had abnormal alanine leucine transaminase and alkaline phosphatase concentrations. The serum bilirubin concentration was abnormal in only one patient: she had cystic fibrosis, an abnormal liver on ultrasound, and splenomegaly. The prothrombin time was abnormal in only two patients, both of whom had abnormal liver scans.

Discussion

Liver involvement in cystic fibrosis occurs in 20 to 50% of patients, depending on age and on what type of pathology is included. Focal or extensive biliary cirrhosis is the most common hepatic abnormality. The histological features are bile duct proliferation and ectasia secondary to obstruction by eosinophilic concretions, and periportal inflammatory cell infiltration. The appearances are specific for cystic fibrosis. In a few cases (approximately 5%) this progresses and a multilobular biliary cirrhosis develops. Pathological examination at this stage shows large irregular nodules separated by massive foci of fibrosis but with areas of preserved architecture. Bile plugged ducts may be present but bile stasis within the lobules is conspicuously rare even in advanced liver disease. The age of onset of liver disease varies. It may present in the neonate but generally it presents later, the mean age of diagnosis being 8-7 years. It may be unrelated to the severity of disease elsewhere but generally there is a tendency for the liver disease to progress with age.

The poor correlation in cystic fibrosis between liver function and liver involvement is due to the focal nature of the liver disease which affects the biliary tracts so that a large volume of liver may be affected before the serum alkaline phosphatase and bilirubin concentrations rise. The serum alanine leucine transaminase determination, being a test of liver cell function, is likewise relatively unaffected.

The serum albumin concentration has been shown to correlate better with the lung function than the liver disease in cystic fibrosis. The prothrombin time may be abnormal because of malabsorption and antibiotic treatment affecting the gut flora.

Only one of our patients had a liver biopsy. We did not consider it justifiable in the other children. In a previous study of liver biopsy in 84 cystic fibrosis patients the liver was affected in 15 (17.8%). There was poor correlation between clinical, biochemical, and biopsy results. Biopsy correlation with liver ultrasound was reported by Willi et al in nine patients with cystic fibrosis who had patchy, irregular, or increased liver echogenicity. In all these the biopsy was abnormal. Ultrasound cannot reliably differentiate the different forms of liver involvement in cystic fibrosis (focal biliary cirrhosis, hepatitis, and cirrhosis) but it may be used as a screen in deciding which patients should undergo biopsy.

Portal hypertension develops in approximately two per cent of patients with cystic fibrosis. In our series we used only ultrasound assessment of spleen size to detect this complication, as explained previously. We do not currently have a combined Doppler B scanner which may be more useful in assessing portal hypertension and direction of flow within the portal veins. Rarely, gastric varices and portal venous collaterals may be detected on ultrasound.

Occasionally the diagnosis of cystic fibrosis is in doubt despite a meticulously performed sweat test, which may be equivocal or very rarely normal. Some of these patients undoubtedly have cystic fibrosis, and if the ultrasonic appearance of the pancreas is obviously abnormal this can be used as further evidence in supporting the diagnosis. Conversely a normal pancreatic appearance in a patient of 5 years or more with suspected cystic fibrosis is further evidence against the diagnosis. Our figures for cystic fibrosis patients of 95% abnormal pancreatic ultrasonic findings over 5 years and 100% abnormal over 5 years with malabsorption are useful in this respect.

We believe abdominal ultrasound is useful in the diagnosis, detection of complications, and follow up of cystic fibrosis patients and plan to scan all our patients at regular intervals. The technique has a place both in documenting the natural history of the condition and monitoring any modification of this that may occur as a result of future treatment.
