Effect of fever on recurrence rate of febrile convulsions

A S EL-RADHI AND S BANAJEH

Paediatric Department, Ahmadi Hospital, Kuwait

SUMMARY We studied 154 children admitted consecutively with their first febrile convulsion to assess the influence of the temperature on the recurrence rate of convulsions. Those with temperatures of 40°C or more were nine times less likely to have subsequent convulsions than those with temperatures of 38–38.9°C.

Factors associated with increased risk of recurrence of febrile convulsions are: the first febrile convulsion occurring before 12 months of age, a history of febrile convulsions in first degree relatives, and the presence of associated complex features of febrile convulsions.1 Little information is available about factors associated with a reduced risk of recurrences. In a previous retrospective study with a limited number of children2 we suggested that a high temperature during the initial febrile convulsions was associated with a decreased incidence of recurrent febrile convulsions. We have expanded the study by including 79 further children prospectively studied since January 1982.

Patients and methods

All children who presented to the paediatric department of this hospital with their first febrile convulsion between January 1980 and February 1986 were included in the study.

The study group comprised 173 children (91 boys and 82 girls). All except four had been born here, so their earlier records were available. Four infants were of low birth weight but had made normal neonatal progress, and the remainder were born at full term with birth weights within the normal range; they had also made uncomplicated postnatal progress.

A febrile convulsion was defined as a generalised convulsion associated with a temperature of more than 38°C that occurred in a child aged 6 months to 5 years who had no pre-existing evidence of neurological abnormalities. All the children were managed consistently according to a routine protocol aimed at reducing body temperature. Paracetamol (10 mg/kg, every four hours) was prescribed for temperatures of over 38.5°C. The rectal temperature was recorded on admission and then every four hours. Routine investigations included a full blood count and cultures from throat, urine, and stool. Blood culture, chest radiograph, and lumbar puncture were not performed unless there were clinical indications. Antibiotics were used if there was evidence suggesting bacterial infection.

The children were divided into three groups according to the severity of the fever recorded on presentation to hospital. Group 1 had temperatures >40°C, group 2, 39–39.9°C, and group 3, 38–38.9°C.

Fifteen children were lost to follow up. Four children subsequently developed afebrile convulsions and were withdrawn from the study. The remaining 154 children were reviewed at three monthly intervals for a mean of 40 months (range 27 to 96).

Results

The groups were comparable with regard to age, sex, and family history of febrile convulsions.

Bacterial infection occurred in 24 patients (16%), 12 in group 1, 10 in group 2, and two in group 3. These infections were tonsillitis (n=2), shigella enteritis (n=4), salmonella enteritis (n=6), otitis media (n=8), pneumonia (n=2), and urinary tract infections (n=2). Antibiotics were not used to treat salmonella and shigella enteritis.

The recurrence rates of febrile convulsions are shown in the table. None of the 11 children who had their initial febrile convulsions after the age of 30 months had a recurrence. The average number of
repeated convulsions continued the initial convulsion. Our results suggest that fever in specific diseases are necessary to determine if fever alone is beneficial, harmful, or without effect. In febrile convulsions it is unlikely that the fever itself or the rate of rise of body temperature are the only precipitating factors. There may be an invasion of virus into the central nervous system in a vulnerable child. Such a virus may trigger antibody response, which protects against reinfection and further febrile convulsion. It is also now well established that fever (by enhancing human host defences) produces various substances that are collectively termed interleukin. Interleukin 1 is known to be pyrogenic and a lymphocyte stimulator. It follows that the amnestic response of the lymphocyte may correlate with the degree of fever and can therefore protect the host from reinfection. In brain tissue the interleukin 1 produced by astrocytes may contribute to such an immunological response within the central nervous system, and play a part in protecting the patient from further convulsions.

Our data suggest that the degree of fever at the time of the initial febrile convulsions might be a useful prognostic indicator of the risk of recurrence of febrile convulsions.

We thank Dr A Mowat, King’s College Hospital, London, and Dr J Wilson, the Hospital for Sick Children, Great Ormond Street, London, for their advice in preparing this manuscript.
