children with coeliac disease. Multiple small intestinal biopsy specimens, perhaps taken endoscopically, may be helpful in establishing the presence of intestinal lymphangiectasia in children with coeliac disease. As intestinal lymphangiectasia may be an incidental finding, additional data, for example the presence of hypogammaglobulinaemia and T cell depletion, may help in determining the clinical significance of lymphangiectatic mucosal changes. These patients with coeliac disease need lifelong diet management.

Positive end expiratory pressure via a portable system in thoracic dystrophy

S Edees, A Moulden, R J Winter

Abstract
The provision of positive end expiratory pressure, via a unique portable system, in the long term management of a child with thoracic dystrophy is reported. The system uses low gas flow enabling a reduction in equipment and simplification of the circuit as compared with a standard continuous positive airways pressure system.

For a child requiring long term continuous positive airways pressure (CPAP), we devised a system for providing positive end expiratory pressure (PEEP) using low flows of oxygen. The system, initially employed to provide CPAP, was a standard high flow Bennett system necessitating that the patient be restricted to his cot on the infants' ward where there are piped supplies of oxygen and air. In order for him to become mobile around the hospital and ultimately at home, we devised a portable PEEP system.

Description of the system
Our system (figure) employed the same CPAP valve and T piece as the high flow pipeline system but required a mixer with a non-return valve to allow the use of low flow oxygen without loss of the PEEP from the valve and to prevent rebreathing. The system consisted of a T piece with an oxygen connector (A) in series with a 1950 non-return valve (B) on one limb, and the CPAP valve (C) on the other limb, the assembly being connected to the infant by a standard 15 mm Portex connector.

The inspired oxygen delivered by the system depends upon the flow of oxygen into the circuit, the respiratory rate, and the inspiratory flow rate of the patient. An increase in the respiratory rate will reduce the time available for oxygen to accumulate in the wide bore tubing during expiration and therefore reduce the fractional inspired oxygen (FIo2). An increase in inspiratory flow will increase the volume of room air entrained via the 1950 one way valve reducing the FIo2. Therefore, the oxygen tension in the circuit cannot be accurately predicted from the present oxygen flow; however, we have found that a flow of 500 ml/min delivers approximately 28% oxygen to our patient. Increasing the flow of oxygen to the circuit up to 1 l/min increases the FIo2 to 36%, and 2 l/min to 48%. Rebreathing is prevented by the presence of the 1950 one way valve and also by the one way valve in the CPAP valve. As flow in the circuit is generated by the child's inspiratory effort the system provides PEEP, not CPAP.

Case report
Soon after birth our patient, now aged 18 months, was noted to have a number of dysmorphic features including the Pierre Robin syndrome (cleft of the soft palate, micrognathia, and glossopatosis), macrocephaly, severe hyphoscoliosis, a small thorax, a penile web attached to the scrotum, and generalised hypotonia.

Investigations were carried out to evaluate his
after introduction of any increase in the respiratory rate.

SYSTEM EFFICACY

After the patient was put onto our system and transferred to a general ward, he remained well. His arterial oxygen tension was maintained at between 9 and 11 kPa and his arterial carbon dioxide tension (Paco₂) remained in the range of 5-5 to 6.5 kPa. There was no rise in the Paco₂ after introduction of the system nor was there any increase in the respiratory rate.

Discussion

There are several of conditions which affect the skeletal and result in abnormal growth of the thorax. The majority of these conditions are rare and experience of management in individual centres is small.

We have been unable to attach an acceptable diagnostic label to this child’s collection of dysmorphic features, and any assessment of his future respiratory function can only be guided by general principles. It has been suggested that the natural history of ‘small chests’ is for the problems to be most severe in the early months of life with gradual resolution if the child survives. The degree of respiratory compromise varies widely between patients even within the same diagnostic groupings.

The rationale for the use of PEEP was to reduce peripheral alveolar collapse and the subsequent ventilation/perfusion mismatch at the end of expiration. The use of long term positive pressure has been previously reported in thoracic dystrophy. In addition to his small chest wall, our patient also has a kyphoscoliosis. In adult patients with this condition lung compliance increases with positive pressure ventilation.

Because the device we have employed uses low flows of oxygen it allows his parents to take the child out of the hospital environment with only a D size oxygen cylinder. It would also be possible to provide flows of this magnitude by using an oxygen concentrator of the type normally used to deliver domiciliary oxygen, so allowing home management.
