true birth prevalence in any one country should be similar to the collective prevalence in Europe or even that in the USA.

The number of cases occurring in a given sample varies randomly around the true population prevalence of the condition: the fact that a score of 100% has been claimed as many as cases would be predicted from the population prevalence does not imply that no cases have been missed.

Is hearing really assessed after bacterial meningitis?

EDITOR,—Dr Fortnum and Professor Hull are rightly encouraged by the results of their survey. Nearly 90% of paediatricians claim to refer all children who have suffered from bacterial meningitis for formal hearing assessment. The authors hope that these good intentions are translated into clinical practice.

Unfortunately this may not be the case. A recent review of bacterial meningitis at our hospital shows that 31% of survivors had no documented hearing test.

Cassettes of children admitted with bacterial meningitis over the eight years 1984 to 1992 were reviewed. Of the 206 identified 156 were available, excluding referral letters. Of these five children died, and 12 (8% of survivors) were later found to have hearing loss. In 49 cassettes (31%) there was no evidence that a formal hearing test had been carried out. Of these six children were not offered any follow up, 11 did not attend follow up, and two moved to other health districts and were lost to follow up. The remaining 39 (19%) survivors were seen as outpatients, but had no documented hearing test result.

There was no significant difference in the proportion of children with no hearing test recorded between the first four years of the study period, and the later four years (not significant by χ²). There was also no trend suggesting recent improvement evident over time.

Who should ensure a formal hearing test is performed on children who have had bacterial meningitis? Improved communication between hospital and community services is required. The introduction of an integrated child health service could prove valuable in this respect.

Near fatal haemorrhage from the superior sagittal sinus in Adams-Oliver syndrome

EDITOR,—We wish to emphasise the danger of haemorrhage from the superior sagittal sinus in association with aplasia cutis congenita of the scalp where there is also a skull defect.

Case report

A boy was born at full term after intrauterine growth retardation had been noted on antenatal ultrasonography. The parents were non-consanguineous and there was no history of maternal drug ingestion. Birth weight was 2080 g with head circumference of 30 cm (below the 3rd centile).

There was a large (4×4 cm) area of scalp aplasia with underlying bony defect (fig 1). The infant also had rudimentary toes and a short left index finger. A diagnosis of Adams-Oliver syndrome was made, and his mother and grandfather were found to have features of the syndrome, which is usually transmitted in an autosomal dominant manner.

The child initially progressed well, but was admitted at age 3 weeks with bleeding from the scalp. When a dressing was removed the scalp ruptured and there was torrential haemorrhage from the superior sagittal sinus, requiring immediate resuscitation. Subsequently, an area of exposed brain 1–5 cm in diameter was noted, with free drainage of cerebrospinal fluid.

A combined neurosurgical and plastics procedure debrided, defined and closed the defect, employing a rotation flap and split skin graft (fig 2). Postoperatively an initial cerebrospinal fluid leakage stopped spontaneously, and prophylactic antibiotics were given for several weeks. His subsequent progress has been uneventful.

Figure 2  Schematic representation of operative findings.

One of the most important findings was the near fatal haemorrhage from the superior sagittal sinus in this case. If this had been left untreated the child’s life would have been at risk.

Discussion

Skull defects may be an isolated phenomenon or associated with Adams-Oliver syndrome. Twenty per cent of isolated scalp defects have an underlying skull defect, whereas in Adams-Oliver syndrome 75% have scalp involvement and 64% of children have skull defects. The complications (infection, bleeding) and management (early closure in cases where the superior sagittal sinus is vulnerable) are similar in both situations.

Neonatal paediatricians should be aware of the potentially life threatening situation when scalp aplasia, underlying skull defect, and secondary infection occur in infants with Adams-Oliver syndrome. Successful closure of the cranial defect can be achieved and a combined neurosurgical and plastics approach is advocated.

Rett syndrome and the 4th metatarsal

EDITOR,—Rett syndrome, an intellectually handicapping, probably genetic disorder affects around one in 10 000 females and is remarkable for the absence of congenital injury, disease or dysmorphism. As early as 1985, one of us (AMK) observed isolated shortening of the 4th metatarsal in some affected girls but not their families. The British Isles Survey for ‘Rett Syndrome’ and clinics organised by the UK Rett Syndrome Association have recently provided an opportunity for serial examinations of cases. Among the last 50 classic cases aged over 5 years, we have observed nine with this solitary anomaly (1 in 5–6 cases). It was not observed in family members. Both feet were usually affected.

We are now examining residents and staff at the Royal Scottish National Hospital (Mental Handicap) as well as further consecutive cases of Rett syndrome and their families to compare prevalence in these groups.

Several disorders involving widespread malformations may include shortening of the 4th metatarsal and an increased incidence of minor malformations is generally expected among the intellectually handicapped population. Ray and Haldane in 1965 observed this solitary abnormality in three out of 2500 in a general male population. From their study of 61 pedigrees, they proposed dominant inheritance with 27% penetrance.

Expression of a local growth anomaly might be attributed to the general growth disorder or to hyperventilation (usual for Rett syndrome and associated with reduced peripheral circula-
