

Prevalence and correlates of obesity in insulin dependent diabetic patients

E Bognetti, P Macellaro, D Novelli, F Meschi, F Ciralli, G Chiumello

Abstract

The prevalence of obesity, according to sex and pubertal stage, and the correlations between obesity and metabolic data were investigated in 286 diabetic patients (164 boys, 122 girls) with mean (SD) age 15.3 (3.2) years and mean (SD) duration of diabetes 7.5 (4.1) years. Prevalence of obesity according to the body mass index (BMI) criteria was 6.3%. Girls were more often obese than boys but the prevalence approached statistical significance only for the BMI criteria, at 9.8% v 3.7% ($\chi^2=3.5$; $p=0.06$); obesity was independent of pubertal stage. Distribution of BMI values of diabetic girls was skewed towards the high centiles of the INSERM tables: <25th centile, 8.6%; 25th–50th centile, 17.3%; 50th–75th centile, 25.9%; >75th centile, 48.2% ($\chi^2=19.17$, $p<0.0005$). BMI values of diabetic boys were homogeneously distributed. Age, duration of diabetes, insulin requirement, daily number of insulin injections, and metabolic control (HbA1c) were comparable in obese and non-obese diabetic patients. Moreover metabolic control and insulin requirements were comparable between diabetic patients with BMI above and below the 50th centile of the INSERM tables after matching for sex. In conclusion the prevalence of obesity in diabetic children and adolescents is quite similar to the prevalence reported in their non-diabetic peers. Obesity and BMI excess correlate with female gender but are independent of insulin requirement and metabolic control.

(Arch Dis Child 1995; 73: 239–242)

Keywords: type I diabetes mellitus, obesity, adolescence, body mass index.

Obesity is not generally thought to be a typical feature of type I (insulin dependent) diabetes mellitus. However, in the United Kingdom, a similar prevalence of obesity was reported in diabetic and non-diabetic children.¹ So far no other studies have been carried out on this subject.

There is interest in childhood obesity because of its increasing prevalence^{2–6} and because of the observation that a large proportion of obese children become obese adults.^{7–9} Moreover obesity in childhood has been associated with many other conditions such as hypertension,¹⁰ respiratory disease,¹¹ cardiovascular disease risk,¹² and psychological problems.¹³

Diet is a common tool in the management of diabetes mellitus as well as of obesity, and poor dietary compliance is often associated with poor metabolic control in diabetic patients and with unsuccessful body weight reduction in obese patients.

The aims of our study were to assess the prevalence of obesity in diabetic patients according to sex and pubertal stage, and to examine the correlations between obesity and metabolic control.

Methods

During a cross sectional study performed on a clinic based population, we consecutively enrolled 286 diabetic patients (164 boys, 122 girls) aged five years or older, who attended our paediatric outpatient clinic and had been diabetic for more than two years. Their mean age was 15.3 (SD 3.2) years and the mean duration of diabetes was 7.5 (4.1) years. All the subjects were receiving short and long acting insulin and were regularly seen at our outpatient clinic.

Height was measured by Harpenden stadiometer (Holtain, UK) and weight was recorded without shoes or outer clothing. Puberty was assessed clinically according to Tanner and Whitehouse^{14 15}: stage 1, prepubertal; stage 2–4, pubescent; stage 5, pubertal. According to this pubertal stage assessment, we enrolled 30 prepubertal patients with mean age 10.4 (1.4) years; 96 pubescent patients with mean age 13.4 (1.7) years, and 160 pubertal patients with mean age 17.5 (2.3) years.

The subjects were regarded as obese when their body mass index (BMI), calculated by dividing weight (kg) by height squared (kg/m^2), was above the 97th centile of the INSERM table, according to age and sex.¹⁶ To compare the prevalence of obesity in our cohort of patients with previously published data, we calculated the predicted weight for height (W/H) and identified obese patients as those in whom W/H was greater than 120%. Since reference growth tables for the Italian population are not available, Tanner's growth tables were used to calculate the W/H of each patient.¹⁷

Glycated haemoglobin (HbA1c) was assessed in the week before the visit by different laboratories; to standardise these results we used the percentage of HbA1c variation above the normal upper limit for each of the laboratories (HbA1c Δ).

Daily insulin requirement was expressed as units/kg body weight.

Data are given as mean(SD). Comparisons between groups were performed by the Student *t* test and χ^2 test. Two tailed *p* values

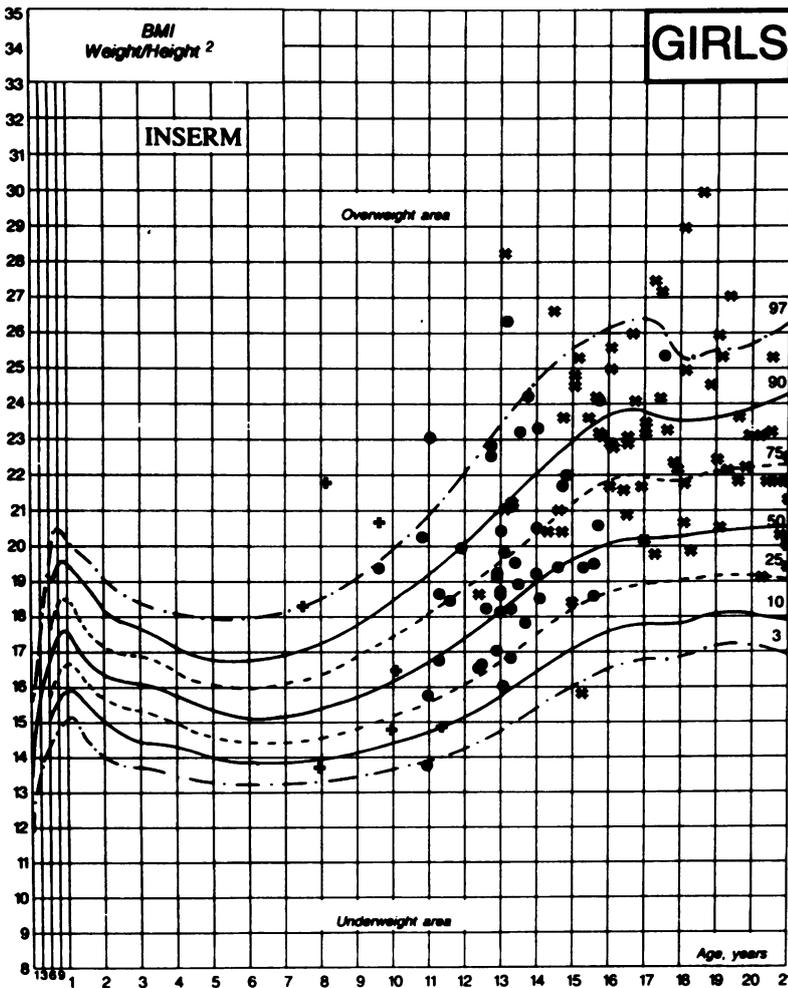

Figure 1 BMI value distribution in diabetic girls according to age and pubertal stage (+ = P1; ● = P2-4; * = P5).

<0.05 were considered significant. Commercially available statistical software was used (Minitab).

Results

According to BMI criteria (BMI >97th centile of the INSERM tables) the overall prevalence of obesity was 6.3% (18/286). The prevalence was higher in girls than in boys, at 9.8% (12/122) v 3.7% (6/164); $\chi^2=3.5$ (p=0.06). There were no significant differences in prevalence of obesity according to pubertal stage: prepubertal patients: 6.9% (2/30); pubescent patients: 2.2% (2/96); pubertal patients: 8.7% (14/160).

BMI values of diabetic girls were skewed to the high centiles of the INSERM tables (fig 1), while BMI values of diabetic boys were more homogeneously distributed (fig 2); the observed number of patients for each centile of the INSERM table was significantly different from the expected number for girls (p<0.001) but not for boys (table 1).

Concordance between W/H and BMI criteria for obesity was higher with the latter: 15 of 18 patients obese by the BMI criteria were also obese by the W/H criteria (83.3%); 14 out of 31 patients obese by the W/H criteria were also obese by the BMI criteria (45.2%).

Age, duration of diabetes, insulin requirement, daily number of insulin injections, and metabolic control (HbA1c Δ) were comparable in obese and non-obese diabetic patients identified according to BMI criteria (table 2).

HbA1c Δ was comparable between patients with BMI values above and below the 50th centile matched for sex: girls, 51.7 (32.2)% v 53.8 (33.4)%; boys, 41.1 (30.2)% v 48.6 (30.6)%.

Insulin requirement was comparable between patients with BMI values above and below the 50th centile matched for sex: girls, 0.82 (0.25) v 0.88 (0.27) U/kg; boys, 0.86 (0.23) v 0.84 (0.22) U/kg.

Discussion

In our study we have analysed the prevalence of obesity in a cohort of diabetic patients randomly enrolled from a clinic based population. Bias may arise from epidemiological studies performed on a clinic based population, particularly when such populations are not representative of the general diabetic population. Our outpatient diabetic clinic follows more than 400 diabetic children and adolescents living in an area with about 1.5 million inhabitants below 18 years of age and a prevalence of insulin dependent diabetes mellitus of around 90/100 000 inhabitants.¹⁸ According to these data, the diabetic population followed by our department is too large to be considered a selected cohort.

In our study the prevalence of obesity was quite comparable with the prevalence reported in the children's non-diabetic Italian peers²⁻⁶ (table 3) and with the prevalence reported by Abusrewil and Savage in the English study,¹ suggesting that obesity in type I diabetic children is frequently observed and is independent of regional dietary habits, at least with regard to Italian and English diets.

The criterion most frequently used to detect obesity is the predicted weight for height (W/H) according to the Tanner growth tables¹⁸ but recently a method based on BMI adjusted for age and sex has been suggested to avoid the interference of age and height changes on weight gain. This method, based on centile distribution tables (INSERM tables), identifies obese subjects when the BMI is above the 97th centile.¹⁶ The INSERM tables were developed in France and no similar tables are available for the Italian population. However the similarity between the French and Italian populations permits their use in our study. The same problem arises with the Tanner tables, developed on the English

Table 1 Distribution of body mass index (BMI) values of diabetic boys and diabetic girls according to the centiles of the INSERM tables. Data are given as absolute numbers and percentage (%). Expected frequency for each centile is 25%

Centiles	Diabetic boys	Diabetic girls*
<25	32 (19.5)	11 (9.0)
25-50	35 (21.3)	21 (17.2)
50-75	48 (29.3)	29 (23.8)
>75	49 (29.9)	61 (50.0)

* χ^2 : 19.17 (p<0.0005).

population but widely used in many countries and recently accepted by an Italian Consensus Conference¹⁹ as the reference tables for assessing predicted weight for height.

Girls were more frequently obese than boys, but the prevalence only approached significance ($p=0.06$) for the BMI criteria; the distribution of BMI values was skewed towards the high centiles of INSERM tables for girls but not for boys. This observation is very different

from the data reported in Italian non-diabetic population, which is characterised by a higher prevalence of obesity in boys than in girls.^{2,3}

In our study, designed to assess the prevalence of obesity, we have not analysed the possible mechanisms involved in excess weight gain. However, resting metabolic rate has not been reported to be modified by diabetes mellitus per se,²⁰ while abnormal dietary habits^{21,22} have been reported more frequently in girls than in boys with diabetes mellitus.

The prevalence of obesity in our cohort was independent of pubertal stage, while in non-diabetic subjects it has been shown to increase significantly with age.² The comparable prevalence of obesity between the younger pre-pubertal diabetic patients and the older pubescent and pubertal patients in our study could be related to the dietary habits of the younger patients. In young diabetic children frequent or excessive snacks are often used to prevent hypoglycaemic episodes, and this could in part explain an excessive weight gain.

According to our data the prevalence of obesity was lower using BMI criteria than using W/H criteria, and concordance for obesity between BMI and W/H was greater in patients identified by the BMI criteria. Therefore we used BMI to identify obesity in the subsequent comparison of the clinical and metabolic variables between obese and non-obese diabetic patients.

In diabetic patients excessive energy intake can easily cause excess weight gain accompanied by metabolic derangement, but weight gain has also been reported during improvement of metabolic control.²³ We did not observe any relation between obesity or BMI values and glycated haemoglobin, insulin requirement as units/kg body weight, or daily insulin schedule, as previously reported by Abusrewil and Savage in the English study.¹ These data suggest that in obese diabetic patients, increases in insulin dosage related to body weight gain may have prevented severe metabolic derangement, but probably assisted in maintaining the excessive body weight.

In conclusion obesity in young diabetic patients, particularly in girls, is not a rare observation. Excessive weight gain should be prevented to avoid the complications associated with obesity and the difficulties relating to its treatment.

Table 2 Clinical and metabolic data of obese and non-obese diabetic patients

	Obese	Not obese
Number (boys/girls)	18 (6/12)	268 (158/110)
Age, years (SD)	15.6 (3.7)	15.3 (3.2)
Duration of diabetes, years (SD)	7.6 (3.7)	7.4 (4.1)
Insulin requirement, U/kg body weight (SD)	0.84 (0.20)	0.85 (0.24)
Two insulin injections/day (%), No)	50 (9)	57 (147)
Three insulin injections/day (%), No)	50 (9)	43 (111)
HbA1c Δ, % (SD)	47.9 (21.1)	47.7 (32.2)

HbA1c Δ = percentage of glycated haemoglobin values above upper limit for laboratory reference values.

Table 3 Prevalence (%) of obesity in children (boys and girls) as reported by other Italian (I) and English (UK) studies. Obesity was assessed by the predicted weight for height method
