Indications for investigation of chronic gastrointestinal symptoms

R M Beattie, J A Walker-Smith, S H Murch

Abstract
Simple routine blood tests (full blood count, platelet count, erythrocyte sedimentation rate, C reactive protein, and serum albumin) may select children with chronic gastrointestinal symptoms who require endoscopic assessment and are thus an important aid in the prediction of endoscopic status. When all of the results are normal then chronic inflammatory bowel disease is an unlikely diagnosis. (Arch Dis Child 1995; 73: 354–355)

Keywords: Crohn’s disease, screening, abdominal pain, C reactive protein.

Colonoscopy is indicated in children with chronic gastrointestinal symptoms in order to diagnose chronic inflammatory bowel diseases, polyps, and less common conditions. Many children who undergo endoscopy are, however, found to have no organic disease. Additionally in Crohn’s disease, the commonest inflammatory bowel disease, diagnosis is often delayed, and despite the availability of paediatric colonoscopy the median time to diagnosis from onset of symptoms is still around 15 months. As the early symptoms of Crohn’s disease are often non-specific, diagnosis is often dependent upon investigations, in particular contrast radiology, endoscopy, and histology. Although abdominal pain is an important symptom of Crohn’s disease, it is also a common childhood complaint. The selection of whom to refer for endoscopy may therefore be difficult: use of screening blood tests to aid in patient selection is therefore likely to be of benefit.

We have audited all tertiary referrals to our unit for diagnostic colonoscopy over an 18 month period (January 1993–August 1994), and correlated the endoscopic diagnosis with the results of easily available screening investigations.

Patients, methods, and results
One hundred and twenty four patients were referred for endoscopic assessment by consultant paediatricians over an 18 month period. In 93 children the diagnosis was uncertain. All patients reported two or more of the following symptoms: abdominal pain, diarrhoea, rectal bleeding, weight loss, or mouth ulceration for greater than three months. The median age of the group was 11 years (range 3 months–18 years) and median duration of symptoms seven months (range 3–60).

One patient was excluded because of short duration of symptoms (two weeks) and one because of orofacial granulomatosis. Thus 91 patients fulfilled the criteria for inclusion. All patients underwent endoscopy and barium follow through at initial assessment. Endoscopic assessment included total colonoscopy and ileoscopy with biopsy. No patient in the study had abnormal radiology with a normal endoscopic assessment and therefore outcome was correlated with endoscopic diagnosis.

Screening variables assessed were haemoglobin concentration, platelet count, erythrocyte sedimentation rate, C reactive protein, and serum albumin, arranged routinely, using standard techniques, by our haematology and biochemistry laboratories.

Diagnosis was established in all 91 children: 26 were found to have Crohn’s disease, 13 ulcerative colitis, eight had polyps, and 37 were normal. Other diagnoses included tuberculosis (2), indeterminate colitis (3), and lymphoid nodular hyperplasia (2).

The results of screening investigations are shown in the table. Overall no child with Crohn’s disease had fully normal screening investigations, although one child with ulcerative colitis had normal investigations despite a clear history of rectal bleeding. Two of 37 children with a normal endoscopic assessment had a raised platelet count and one was anaemic.

Discussion
Our results show that simple routine blood tests may be valuable in the selection of children with gastrointestinal symptoms who require endoscopic assessment. In particular all children with undiagnosed Crohn’s disease had a C reactive protein greater than 5 mg/l. Normal indices do not invariably mean that endoscopy will be normal: either polyposis or ulcerative colitis may be present. However, most of these patients have rectal bleeding which should make colonoscopy mandatory. The diagnosis of Crohn’s disease is unlikely if screening investigations are normal, but should be strongly considered if these indices are abnormal. The diagnosis of ulcerative colitis is unlikely if the indices are all normal and rectal bleeding is not present.

The role of blood tests in the assessment of known chronic inflammatory bowel disease is well established. Harris et al focused particularly on the platelet count as a marker of inflammatory activity in Crohn’s disease. We have found the C reactive protein to be the most sensitive inflammatory indicator at diagnosis. C reactive protein reflects the systemic response to locally produced cytokines from...
Barium meal and follow through is a more readily available investigation. Endoscopy with biopsy, in addition to small bowel radiology, however, is worthwhile in order to assess disease extent – which may influence treatment – and to confirm the diagnosis.

We suggest that these simple tests should be performed early in all children with chronic gastrointestinal symptoms. Abnormalities suggest the need for early referral, whereas normal investigations and no history of rectal bleeding make chronic inflammatory bowel disease unlikely. This policy should lead to swifter diagnosis in children with inflammatory bowel disease and may spare many others invasive investigations.
