Differential avian and human tuberculin skin testing in non-tuberculous mycobacterial infection

A J Daley, D Isaacs

Abstract

Objective—To determine the sensitivity of differential avian and human delayed-type hypersensitivity skin testing in the diagnosis of non-tuberculous mycobacterial lymphadenitis.

Method—Retrospective review of all patients with culture proven non-tuberculous mycobacterial lymph node infections who also had differential avian and human skin testing performed over a 10 year period from 1986 to 1996.

Results—One hundred and twenty four patients had non-tuberculous mycobacteria isolated from lymph nodes over this period, 59 of whom had differential skin testing performed. The sensitivity of a response of ≥ 10 mm to the avian precipitin was 58 of 59. No patient had both a negative human and avian Mantoux. The sensitivity of the human Mantoux alone for diagnosing non-tuberculous mycobacterial infection was 81% for a response of ≥ 5 mm and 66% for ≥ 10 mm. Ten patients had a 0 human response. Fifty five of the 59 patients had an avian response at least 2 mm greater than the human response.

Conclusion—The avian Mantoux is a very sensitive method of diagnosing non-tuberculous mycobacterial infection in children. The human Mantoux is not sensitive enough to be used alone as a surrogate to diagnose non-tuberculous mycobacterial infection.

Keywords: non-tuberculous mycobacteria; Mantoux; lymphadenopathy

There are more than 30 different mycobacterial species other than those in the human Mycobacterium tuberculosis complex. Several different names have been used to identify this group of organisms since their first description by Runyon in 1959, including non-tuberculous mycobacteria, atypical mycobacteria, anonymous mycobacteria, mycobacteria other than tuberculosis (MOTT), and unclassified, environmental, non-pathogenic and opportunistic mycobacteria.

The commonest presentation of non-tuberculous mycobacterial infection in children is as head and neck lymphadenopathy. Cervical lymphadenopathy, however, is relatively common in children and the clinical features of malignancy, salivary gland disease, and various viral, fungal, and bacterial infections including M tuberculosis all overlap to some degree. A rapid and simple method for the diagnosis of non-tuberculous mycobacterial infection would have considerable clinical value because the management of the conditions varies according to the diagnosis. Furthermore, in certain situations, such as with lesions in the parotid area, excisional biopsy may lead to morbidity from facial nerve damage. We undertook this retrospective review of culture proven non-tuberculous mycobacterial infections to determine the sensitivity of skin testing with both avian sensitin and human tuberculin in children.

Methods

A retrospective review was performed of all patients with culture proven non-tuberculous mycobacterial lymph node infections who also had differential avian and human skin testing performed over a 10 year period from 1986 to 1996.

Specimens consisted of lymph node biopsies and pus swabs from various anatomical sites. All clinical isolates were forwarded to a reference laboratory for identification. From 1992 the species of non-tuberculous mycobacterium was available; before this the isolates were classified only into the Mycobacterium avium-intracellulare-scrufulaceum (MAIS) group.

Avian and human tuberculin purified protein derivative (PPD) was obtained from the Commonwealth Serum Laboratories Limited (CSL, Parkville, Melbourne, Australia). The human tuberculin PPD was manufactured from killed M tuberculosis and the avian PPD from killed M avium. Both were prepared as a solution of the protein derivative in phosphate buffer with 0.5% wt/vol phenol as a preservative and 0.005% vol/vol Tween 80 as a stabiliser. These preparations were tested for potency in sensitised guinea pigs and standardised against the World Health Organisation’s first international standard tuberculin. The current tuberculins supplied by CSL in Australia have been available for over 30 years and the method of manufacture has not changed over this time. No other tuberculins have been available in Australia for routine testing during this period (CSL, personal communication, 1998).

The avian and human tuberculins were used at a strength of 100 IU (0.002 mg)/ml with a dose of 10 IU (0.1 ml or 0.0002 mg) administered intradermally via a 26G needle using a 1 ml tuberculin syringe into the ventral surface of the upper part of each forearm (by convention the avian in the right forearm and the human in the left forearm).
induration was measured at 72 hours by a trained member of staff and recorded. No patient had significant vesiculation or ulceration at the test site.

The interpretation of both the avian and human results was based on the National Tuberculosis Advisory Council (Canberra) recommendations as follows: negative, < 5 mm diameter; weak positive, 5–9 mm diameter; intermediate positive, 10–14 mm; and strong positive, ≥ 15 mm diameter with or without vesiculation.

Discussion

The diagnosis of non-tuberculous mycobacterial infection is based on a high level of clinical suspicion, appropriate delayed-type hypersensitivity skin testing, and, ultimately, excisional biopsy of the nodes with histological and microbiological confirmation. Fine needle aspiration has also been used for diagnosis with some success.

Skin testing with PPD from M tuberculosis at a strength of 5 IU (international tuberculin units) commonly produces a positive reaction of between 5 and 10 mm in children with non-tuberculous mycobacterial infection. This is a result of cross reaction with antigens present on the non-tuberculous mycobacteria. In areas where the prevalence of tuberculosis is low, this crossreaction has been used as a surrogate test for non-tuberculous mycobacterial infection but may in fact lead to diagnostic confusion.

Several studies have attempted to assess the sensitivity of the avian Mantoux but these also included patients in whom the diagnosis was not proven on culture. Wright has recently published his Australian experience. All but one of his 67 patients had an avian Mantoux performed but only 29 of his patients had culture proven non-tuberculous infection, the other diagnoses being based on “diagnostic histology”. A total of 63 of 66 patients had an avian Mantoux > 10 mm, giving a sensitivity of 95% for the avian Mantoux. There were three false positives, with the final diagnoses being cat scratch disease, pilomatrixoma, and “non-specific lymphadenopathy”. Only 14 of 56 patients had a positive human Mantoux of > 10 mm to 10 IU human PPD.

We were unable to estimate the specificity of the avian Mantoux because we did not have a sufficient number of children with other proven infections who had differential avian and human Mantoux testing performed. In any study it is difficult to exclude non-tuberculous mycobacterial infection completely, even if another diagnosis is made.

Different preparations of avian and human PPD are used and at different strengths (5 IU in North America, 10 IU in Australia and the UK). There is no evidence as to whether these differences alter the reliability of the Mantoux test. Our results on the sensitivity of the avian Mantoux were similar to those obtained by Margileth in 1983. As part of a larger study on the use of non-tuberculous mycobacteria for skin testing, he investigated 26 patients with culture proven MAI infection, 23 of whom had a reaction to the non-tuberculous sensitin at least 2 mm and in 52 the result was greater by at least 3 mm (fig 1).
least 3 mm greater than the corresponding human PPD reaction. He also found that a fifth of these patients had a negative reaction to human PPD. In a small study of five children with culture proven non-tuberculous mycobacterial infection, Del Beccaro found that all children had a response of > 15 mm to the M avium complex antigen used.11

Because of the small number of children with proven M tuberculosis infection seen at this hospital, we were unable to compare their reaction with both the human and avian antigens. Margileth was able to do this for 22 patients and found that all had a positive human Mantoux of >15 mm and none had an avian result greater than the human one.10

The best sensitivity in our study was obtained using an avian cut off point of ≥ 10 mm and having the avian result equal to or greater than the human result. If we used a definition of a positive result being when the avian response was greater than the human response by 2 mm or more, the sensitivity was 93%; if we used a definition of the avian response being at least 3 mm greater the sensitivity was 88%. Using a cut off of >15 mm for the avian Mantoux may increase the specificity but decreased the sensitivity to 81% in our study.

Our study demonstrates that in countries with a low incidence of tuberculosis, the avian Mantoux is a very sensitive method for confirming the clinical suspicion of non-tuberculous mycobacteria as a cause of childhood lymphadenopathy. The use of the human Mantoux alone as a diagnostic tool is much less sensitive in this situation and potentially confusing. In areas where tuberculosis is prevalent, the differential human and avian Mantoux may be a useful aid to diagnosis.
