Cystic fibrosis related low bone density

We were interested to read the study by Laursen et al which highlights the important problem of decreased bone mass in the cystic fibrosis population. The authors found that reduced bone size was primarily responsible for the decreased bone mass observed in patients ≤19 years old. These results are at variance with the findings of Gibbens and colleagues, who, using quantitative computed tomography, showed that the volumetric (three dimensional) lumbar spine bone density of children with cystic fibrosis was 10% lower (p<0.001) than in local controls.

Although these contrasting results may partially reflect true differences in bone mass between the study populations, they may also be due to regional differences in bone mass. In addition, quantitative computed tomography measurements in the spine are confined to cancellous bone whereas total body dual energy x-ray absorptiometry measurements, as used by Laursen et al, predominantly reflect cortical bone. Both measurements are therefore useful, but contribute differently to our knowledge of the skeleton. Another recent study supports the fact that the reduced areal (two dimensional) bone mass density documented in young patients with cystic fibrosis is due to a combination of decreased volumetric bone mass density and reduced bone size, rather than reduced bone size alone. We would therefore suggest that it is important to monitor the skeletal health of patients with cystic fibrosis (starting in childhood), ideally by performing annual bone densitometry. As fractures involving trabecular sites such as the ribs and spine are more prevalent in adults with cystic fibrosis than in the general population, regional rather than total body bone mass density assessments should be performed to more accurately assess fracture risk.

Non-familial short stature

Non-familial short stature

Professor Cole comments:

Mulligan and Voss are concerned that the conditional chart does not identify hidden pathology, but they misunderstand the chart’s purpose. It is designed for short children of tall families, not short children of short families—this group is already catered for in the unconditional chart. All the Wessex Growth Study cases of hidden pathology had shorter parents than average, so the conditional chart is not intended for them. Short children from tall families are relatively uncommon, so the cost of the extra screen is modest.

Despite what Mulligan and Voss say, familial heights do not have to be measured—it is obviously desirable but not essential. Precision of measurement is much more important for the child than for the other family member(s), due to the shape of the critical region on the chart. And the father is not essential for the assessment—the chart uses whatever family size information is available.

Figure 1 Height standard deviation score (SDS) of children with “silent” pathology plotted against mid-parental height SDS. Three children had a height on or above both the unconditional and conditional 0.4th centile.

www.archdischild.com
What Mulligan and Voss seem to be concerned about is the use of the 0.4th rather than the 2nd unconditional centile. It certainly increases the number of cases of pathology missed, but it also reduces the false positive rate by five sixth. Either way it has nothing whatever to do with familial height adjustment.

Physical treatment of fever

Editor,—I read with interest the paper by Pursell,1 and am in agreement with his conclusion that tepid sponging offers little advantage over the administration of paracetamol alone in most cases. I would go as far as saying that tepid sponging offers no advantage in the vast majority of cases. We no longer use fans and sponging, but remove some clothing (keeping a vest or a light T-shirt) during the phase of defervescence and sweating. We have not experienced any disadvantages with this current practice. There are important points to mention that are missing in this paper. Why is there a need to lower the body temperature with tepid sponging even further than can be achieved with paracetamol? When we "treat" fever vigorously by combining an antipyretic drug with physical methods, we are giving the impression to parents, students, junior doctors, and others, that fever is harmful and the antipyretic is the most effective. The scientific evidence does not support this practice. It is the underlying disease, not the fever, which we should be concerned about. The presence of fever could well be of benefit to the infected host through the activation of the immune system. Several clinical studies have shown the beneficial effects of fever,1,2 even high fever over 40°C,3 and the harmful effects of the antipyretic.4 We prescribe antipyretics because of prevailing concepts among physicians, parental expectation, and because children may show improvement in their level of activity and alertness.

Physical methods have an important indication in cases of hyperthermia, such as heat stroke, where antipyretics are ineffective. Hyperthermia can also complicate febrile illness (vigorous muscular contractions in a child with febrile convulsion) and physical treatment may be of benefit.

Several issues remain unresolved. Which diseases are likely to benefit from the presence of fever, so that minimal interference is indicated? What degree of fever is harmful and thus ought to be lowered? Finally, does antipyretics have any effect on the clinical course of infectious diseases?

Guidelines for the ethical conduct of medical research involving children

Editor,—The new guidelines1 and the commentary by Professor Sir David Hull have highlighted the difficulties and problems of blood analysis in the paediatric population. However, I would like to point out that blood analysis is a very common practice in everyday paediatrics compared to its rarer use in research. Unfortunately, most of the blood analysis in everyday practice is carried out by junior house officers, under excuses such as “routine investigations”, often without consultation with more senior members of staff and full explanation either to the older child or to the parents as to the necessity of such investigations. I just wonder whether it is more appropriate for the college to issue guidelines on the appropriateness of investigations in the childhood population.

The role of lumbar puncture in meningococcal disease

Editor,—The numbers of cases of meningococcal disease diagnosed clinically and by polymerase chain reaction (PCR) have increased, while the number of confirmed cases and lumbar punctures are falling.1,2 This changing trend in case ascertainment was noted by Gill.3 Pollard et al seem to support this trend,4 preferring to avoid lumbar puncture in all patients with clinically obvious meningococcal disease because it adds little useful information to the clinical diagnosis, it could be misleading, and does not affect clinical treatment.5 I find this surprising for several reasons.

Firstly, it is at odds with their view on treatment, that a broad spectrum third generation cephalosporin should be used “until microbiological information is available” and possible penicillin resistance or alternative bacterial causes of purpura are excluded. Cerebrospinal fluid (CSF) may provide this information, and could thus contribute significantly to diagnosis and management. Also, identifying a bacteria other than meningococcus or Haemophilus influenzae would avert unnecessary antibiotic prophylaxis of contacts.

Secondly, PCR microscopy could confirm the diagnosis of meningitis within the hour. Blood and throat cultures take at least 12 hours; and although PCR itself only takes 2 hours,1 in practice the need to transport the sample to the Meningococcal Reference Unit in Manchester may deny results for several days. It must benefit clinicians and the patient’s family to have the diagnosis confirmed quickly.

Thirdly, isolating the causative meningococcus does not just make the microbiologist happy, it can also provide valuable clinical and epidemiological information. PCR of blood can identify the capsular serogroup, but the actual organism is required to determine antibiotic sensitivities and other phenotypic characteristics. Compared to blood (54% (88/164)) and throat (31% (96/315)) culture, CSF (70% (96/138)) offers the highest chance of isolating meningococci, particularly when pre-admission antibiotics are given.2,3

Finally, an initially normal CSF is well recognised in meningitis cases and should be no more misleading than an initially normal white blood count or C reactive protein. Therefore, in the absence of contraindications, it can be helpful to transport the sample to the Meningococcal Unit in Manchester, as it may provide this information, and could thus contribute to the diagnosis and management of meningococcal disease.

A short stay observation unit improves care in the paediatric emergency care setting

EDITOR,—The number of admissions to hospital emergency departments is increasing, by up to five per cent a year.1 Most of these children are under 5 years of age, and they may come straight to hospital without any preceding medical examination.2 Although a short stay observation unit (SSOU) has been proved essential for a good emergency service,3 few publications have looked at its influence on the admission rate in paediatrics.4 We analysed the activity of a SSOU opened in 1992 in the paediatric emergency department (PED) of the Children’s Hospital of Bordeaux. We also looked at the number of total admissions to the PED and the number of children admitted to paediatric wards between 1987 and 1996.

Among 2321 patients admitted to the SSOU in 1996, we analysed 644 medical patients (table 1): 55% of children were under 3 years old, 70% living in the town or surroundings, and only 36% referred by a general practitioner. Twenty per cent were admitted for diagnosis (group A), 50% for treatment and observation of a pre-diagnosed acute condition before deciding on discharge (group B), while 30% were waiting for a bed on a paediatric ward (group C). Sixty eight per cent of children spent less than six hours in SSOU, and 79% of those from groups A and B were thereafter discharged. Between 1987 and 1991, the number of medical referrals to the PED gradually increased by an average of 8.25% per year (fig 1). Similarly, admissions to paediatric wards increased by 5% per year, from 2467 in 1987 to 3541 in 1991 (fig 2). Since its opening in 1992, the activity of the SSOU increased dramatically, reaching 2141 medical admissions in 1996 (fig 2), representing a mean occupancy rate of 146%. Interestingly, although the number of medical visits to the PED continued to increase during that time (fig 1), the increase in admissions to the wards stopped, and even decreased a little from 1995 (fig 2).

Our study demonstrates the clear effectiveness of a SSOU in limiting the number of admissions to a tertiary paediatric centre.

The opening of the SSOU in our hospital's PED allowed us to control the increase in inpatient admissions even though the number of medical referrals to the PED was still going up. This meant that inpatient wards were less overburdened by emergency inpatients, who generally stay a short time in hospital, but disturb work in the specialised wards. In addition, inpatients are generally assessed by medical staff twice a day only, which may result in unnecessary delays in discharge. On the contrary, continuous observation and repeated assessments of those admitted to the SSOU facilitated more rapid discharge. The shorter length of stay in this unit reduces the risk of hospital acquired infections and limits childrens’ and parents’ anxiety.
