If you have a burning desire to respond to a paper published in *Arch Dis Child* or *F&N*, why not make use of our “rapid response” option? Log on to our website (www.archdischild.com), find the paper that interests you, click on “full text” and send your response by email by clicking on “submit a response”.

Providing it isn't libellous or obscene, it will be published (subject to editing) in *Arch Dis Child* or *F&N*, why not comment on “full text” and send your response by email by clicking on “submit a response.”

The editors will decide, as before, whether to also publish it in a future paper issue.

Hypoxaemia in children: “abnormal” values may be misleading

Duke et al are to be commended for their interesting report aimed to determine normal oxygen saturation values in healthy infants and children and to assess the performance of clinical signs for predicting hypoxaemia in sick neonates and children with and without acute lower respiratory infections (ALRI). Acute lower respiratory infections (ALRI) account for a substantial burden of disease in children and adults, pneumonia being the leading cause of deaths in children under five, particularly in developing countries. Tachypnoea and chest retraction have been shown to be the most useful clinical signs for determining the presence of pneumonia and thus they are widely used in the diagnosis and management of this condition in children. The World Health Organization pneumonia case detection and management programme, which relies on these simple signs, seems to be justified by the existing body of evidence.

Varying degrees of hypoxaemia may be present in children with pneumonia. However, surprisingly few studies have been performed to assess normal values of haemoglobin oxygen saturation (SpO2) through the use of transcutaneous pulse oximetry, at both sea level and high altitude. Singh’s response to Duke et al rightly emphasises that altitude of studies reported must be taken into account in the interpretation of their results. There are some reports on SpO2 values at mid- and high altitude settings in healthy and sick children. We previously reported normal values of SpO2 in 1264 healthy children and adolescents living at 4100 m.

The main conclusions of these studies performed at different altitudes are: firstly, values considered abnormal at sea level are very frequently found at high altitude in healthy children; secondly, normal values vary for different altitudes; thirdly, recommended SpO2 cutoffs giving supplementary oxygen to sick children at sea level are clearly not applicable to high altitude settings, as according to these recommendations oxygen should be administered for values below 92%. There is a need to perform more studies for determining which cut off values for supplementary oxygen are related to better outcomes in sick children living at high altitude. Moreover, our study at 4100 m revealed that SpO2 values may be different according to different ethnic groups and history of exposure to high altitude. Higher SpO2 values in Quechua children suggest a better degree of adaptation to high altitude in native populations with a longer time to exposure to high altitude. This latter finding has obvious practical implications, as high altitude native children, with higher baseline oxygen saturation levels than newcomers or resident non-native children, require oxygen at a higher cut off SpO2 values when they are sick.

Singh is justifiably concerned on the cost of giving oxygen to children who may not need it. Oxygen may be unacceptably expensive for health services in developing countries, particularly at primary level, where most sick children seek health care. However, hypoxaemia may be a serious, life threatening problem in sick children, particularly at high altitude, and thus we reported the study of Duke et al for different altitudes, in healthy and sick infants and children, to determine normal values of SpO2, and to identify highly predic- tive clinical signs of hypoxaemia. The potential aggravating role of co-existing prevalent childhood diseases other than ALRI, namely diarrhoea, malnutrition, malaria, and HIV/AIDS, is also an area that warrants more attention. These data will allow providing both good quality and cost effective health care to sick children with and without ALRI. Millions of children and adults live at high altitude. Developing a medicine based on scientific evidence that can be applicable to this setting is a major public health challenge for all of us working in those parts of the world.

Response to Duke et al

We read with interest the article by Duke et al regarding hypoxaemia in acute respiratory and non-respiratory illnesses in infants and children in developing countries published recently in *Archives.* The authors have rightly pointed out the limited availability of published data on the incidence, significance or clinical signs predicting hypoxaemia in infants less than three months of age. With similar concerns we had conducted a study in infants less than two months, a part of which was published in the *Archives.* We found that tachypnoea, defined as RR > 60/min, predicted hypoxia with 80% sensitivity and 68% specificity. In that study we identified six functional and behavioural responses as predictors of hypoxaemia (table 1). Five of these six variables had a very good sensitivity to detect hypoxaemia.

A very high prevalence of hypoxaemia in the population studied by Duke et al is rather intriguing. Out of total 257 sick neonates and children 52%, were hypoxemic. Among children with acute lower respiratory infection (ALRI) 73% and those with non-ALRI 32% were hypoxemic. In an ongoing study we have measured oxygen saturation (by Nellcor® oximeter) in a prospective cohort of 683 children 2–59 months brought to paediatric emergency department (ED) with any respiratory symptom. Oxygen saturation using a fingertip sensor in these children at the time of arrival to ED ranged from 78–99%. The overall prevalence of hypoxaemia defined as SpO2 <90% was 4.5% (table 2).

An additional 5.1% children had borderline hypoxaemia, i.e. a SpO2 value of 90%. This is similar to a prevalence of 5.9% hypoxia (defined as SpO2 <90%) in Gambian children, 2–33 months of age, reported by Usen et al. Even in our previous study of 200 infants less than two months, only 38.5% of the sick infants attending ED were hypoxemic. A systematic review of studies on prevalence and predictors of hypoxemia in children by Lozano et al found that the prevalence of hypoxia was dependent upon a number of factors including the setting of the study. The prevalence ranged from 6–9% in outdoor setting to 31–43% in emergency departments to a maximum of 47% in hospitalised children. Yet, in our study, which represents the situation near sea level (Chandigarh being a plain topographically) and the setting of an emergency department, the prevalence of hypoxaemia is much lower than that reported at heights. In light of our data and published literature we believe that either the definition of hypoxemia used by Duke et al is too liberal or the children with respiratory symptoms living at high altitude decompensate more frequently to develop hypoxia. More information is needed in this respect to formulate
guidelines for general use. The cumulative data clearly suggest that hypoxaemia is more frequent in children living at high altitude. Interestingly most studies including that of Duke et al. on this subject in children 2 to 59 months have been from high altitudes. It is unlikely that geographic location, 1600m above sea level is responsible for the high frequency of “hypoxaemia” in their patient population. This, however, may not necessar-ily be the case for oxygen therapy. A consideration about SpO2 cut off for hypoxia at higher altitudes is needed. An additional source of selection bias. The much lower overall prevalence of hypoxaemia seen by Drs Singhi and Bharti in their emergency department population is therefore understandable. Of note the prevalence of hypoxaemia among sick neonates admitted to Goroka Hospital (43%) was similar to the prevalence among young infants (<2 months of age) attending the emergency department in Chandigarh (38.5%).

It is interesting to consider the effects of altitude on hypoxaemia in children with pneumonia. Some populations living at higher altitudes may have a greater tendency to pulmonary hypertension; this susceptibility may be genetically determined and supports Dr Huicho’s statement that ethnic differences in SpO2 at the same altitude are important. At altitude in response to hypoxia, pulmonary blood flow is shunted to the lung apices associated with an exaggerated vasoconstric- tion in the basal lung. This may have an adverse effect on ventilation perfusion match- ing in the supine position. In addition cardiac expression of natriuretic peptides increases in parallel with pulmonary artery pressure. These and other pathophysiological changes may account for the greater severity and pro-longed duration of hypoxaemia seen at higher altitudes.

It is important to evaluate the simple intervention of nursing children with pneumonia and hypoxaemia at high altitude in an inclined head-up position, rather than supine, to determine if this reduces the sever-ity of hypoxaemia. There is a need for more evidence about the prevalence of hypoxaemia at sea level and different altitudes; which children benefit from oxygen; for how long oxygen should be given and the best ways to deliver oxygen in remote settings. Controlled trials of oxygen in mild hypoxaemia may not be justified for ethical reasons, but other evidence will be informative. Before the intro-duction of pulse oximetry in Goroka we used the World Health Organization guidelines for giving oxygen (cyanosis, inability to feed or severe respiratory distress). With the intro-duction of pulse oximetry we set a threshold for giving oxygen at SpO2 85%. The severe pneumonia case-fatality rate fell from 10% (26/258) pre-pulse oximetry to 5.8% (65/ 1116) 2 years later.14 In highland PNG children cyanosis was only detected in 44% of those with an SpO2<90%.15 Although there will be confounders in the before-and-after analysis of outcome, we conclude that clinical signs must miss a significant proportion of children who would otherwise benefit from supplemental oxygen. We refer to a protocol for the administration of oxygen based on a threshold SpO2 of 85% (more than 3 SD below the mean for normal children in Goroka) resulted in improved outcomes, and was within available resources.

The costs of oxygen and logistics of transporting cylinders are major problems in many developing countries; Dr Huicho is right that these are important public health chal-lenges. They call for innovative research and development into how best to supply oxygen to children who need it. The role of oxygen concentrators need to be further explored; the combination of concentrators with pulse oximetry would be appropriate technology for many hospitals in developing countries. Increasing the availability of oxygen concentrators at a cost that is crucial to the management of more than 20% of children hospitalised worldwide should be a very high priority; oxygen is one such drug.

Refugee children: don’t replace one form of severe adversity with another

We strongly agree with Fazel and Stein’s view that refugee families require help that is culturally sensitive. Failure to provide appro-priate interventions in a culturally sensitive way to these children and their families means we potentially replace one form of severe adversity with another. Contrary to Fazel and Stein’s positive view of school such adversity may include, for some children, integration into the UK educational system. While we agree that psychological trauma can be identified in significant numbers of refugee children, many will have qualities of “resilience” that will have been highly developed by their experiences of war and other adversities prior to their arrival in this country. Having
Pharmacogenomic can give children safer medicines

I read with great interest Clarkson and Choonara’s paper on the fatal suspected adverse drug reactions (ADRs) in the UK, and I strongly agree with their conclusions, namely that an evidence based approach to drug treatment is needed to minimise fatalities due to drug toxicity in children. However, recent evidence also suggests that we are now ready for the gene based approach to drug treatment allowing to further minimise the occurrence and the severity of adverse drug reactions. Increasingly complex genetic knowledge can already be used to elucidate mechanisms underlying the adverse events of drugs. Ketoacid levels may alter osmoticity in diabetic ketoacidosis and precipitate cerebral edema

Inward and Chambers have called for a rethink of the management of diabetic ketoacidosis. In their article they quote a study by Grove L M and colleagues that pediatricians overestimated the quantum of fluid and sodium administration) were associated with the risk of cerebral edema, their data did not support the theory that a rapid decrease in extra cellular osmolality during treatment results in osmotic mediated swelling. Osmolality and osmolar gap were not measured, nor was ketone body levels studied (personal communication, Glaser N ). Our studies demonstrate that the ketone level is probably a “relevant variable” that needs to be estimated before we can be certain that rapid decrease in extracellular osmolality did not occur. In summary we suggest that changes in ketone body levels be considered, as a factor that can be partially responsible for the cerebral edema often seen during treatment of DKA. We will be glad to share our data at any summit of experts convened to study the enigma of cerebral edema in DKA.

**The Lazarus case, Life and Death Issues in Neonatal Intensive Care**

When things go badly wrong in the perinatal period there has developed a culture in many “advanced societies” that demands a search for someone to blame. This search for guilt, accountability, punishment, and recompense often results in litigation.

In this thought provoking book John D Lantos describes such lawsuits as “our public morality plays” and uses his experience as a neonatologist, expert witness, and ethicist to create, debate, and crystallise relevant issues of ethics related to the neonatal intensive care of a fictional preterm infant who should have died but did not—*The Lazarus Case.*

A fictitious neonatologist, Dr Miller, decides to stop resuscitation of a very preterm infant who seems past reasonable care. The baby who might have died survived with severe neurological problems and the parents sue Dr Miller, alleging that stopping treatment was negligent. John Lantos places himself in the role of expert witness and uses questions put by the plaintiff’s lawyers to explore the moral, ethical, legal, and social factors and to illustrate the ambiguities, misunderstandings, responsibilities, and evasions highlighted by the perinatal care of a 25 week gestation infant.

A key question put to Dr Lantos by one lawyer was “Can studying philosophy tell you whether what a doctor does in a particular case is right or wrong?” Probably not is the final conclusion reached by Dr Lantos, but it was just as unlikely that definitive guidance would come from sociology, religious doctrine, strict medical protocols, or any other single source.

There have been many attempts over the past half century to face and explain the moral dilemmas associated with our attempts to save the lives, prevent damage, and encourage optimal development of critically ill preterm infants. *The Lazarus Case* reviews in a most effective, compelling, erudite, and compassionate way the enormous complexity of these issues. It is highly recommended to all who are concerned with the care of preterm infants and their families and is essential reading for those required to provide medico-legal advice on life and death issues in neonatal intensive care.

**Problems in Paediatric Drug Therapy, 4th edn**

There is increasing interest in both the clinical and scientific aspects of drug therapy in paediatric patients. This text book by the American Pharmaceutical Association is aimed at the North American market.

It is a reference book aimed at paediatric pharmacists. It covers a wide range of the problems associated with paediatric drug therapy, with chapters on the administration of drugs, fetal toxicity, drugs in breast milk, and both poisoning and drug toxicity, and also specific clinical areas, for example chemotherapy. There did not appear to be any order in the chapters. It would seem more appropriate to put chapter 13 on neonatal doses after chapter 3 on drugs in breast milk than after a chapter on chemotherapy.

There are several chapters with information on the dosage of medicines and it is of interest that these are divided into three separate chapters, one for neonates, one for infants/children and adolescents and one specifically for intravenous drugs. Despite having a chapter specifically on intravenous drugs, the chapters on drug dosing on both neonates and infants/children and adolescents contains details on the doses required for intravenous administration. This makes the book far more difficult to use. The dosage guidance is far less user friendly than publications such as Medicines for Children or the Neonatal Formulary.

It is for this reason I would not therefore recommend Paediatric Pharmacy departments to buy a copy of the book.
