Another case of HBV associated membranous glomerulonephritis resolving on lamivudine

Connor and colleagues (see page 446) report rapid resolution of a hepatitis B associated membranous glomerulopathy and nephrotic syndrome after two months of oral lamivudine. We would like to add our experience in a similar case.

A 5 year old female of Vietnamese origin presented with a two week history of periorbital swelling and weight gain. She had 3 plus protein, 10–20 dysmorphic red blood cells and red blood cell casts in her urine. Serum albumin was low at 19 g/l, cholesterol was 9.8 mmol/l, and serum complement C3 and C4 were reduced (0.61 g/l and <0.1 g/l, respectively). She was hepatitis B surface antigen positive and hepatitis B surface antibody negative. The physician caring for her at that time placed her on prednisone 60 mg/m²/day in three divided doses, and referred her to our service six weeks later, as the nephrotic syndrome was unresponsive to steroids. Her viral load initially was 1090 pg/ml of hepatitis B DNA in peripheral blood, and rose to >2000 pg/ml after four weeks of steroids, when ALT peaked at 72 U/l. A renal biopsy revealed stage II membranous glomerulonephritis. A liver biopsy showed focal lobular and portal inflammation and changes consistent with a mild chronic hepatitis.

She was started on lamivudine at a dose of 50 mg once daily (2.5 mg/kg), with steroids being weaned off over four weeks. Two weeks later the hepatitis B DNA dropped to 1686 pg/ml, decreased to 7 pg/ml two months later, and was undetectable at three months.

She continued to be hepatitis e antigen positive without detectable e antibodies. The patient’s proteinuria was cleared after three months of treatment, and serum albumin remained normal thereafter. She continued to take lamivudine for 13 months without rebound proteinuria. Six months after discontinuing lamivudine she remained clinically well, her urinalysis showed 0.04 g of protein per 24 hours, and there was microscopic haematuria. Hepatitis B DNA rose to >2000 pg/ml, indicating continued active viral replication. A repeat renal biopsy showed multiple electron dense deposits which had been incorporated into the lamina densa with fragmentation of the latter, consistent with a membranous glomerulonephritis stage II/III. She has evidence of hyperfiltration with a glomerular filtration rate of 163 mL/min/1.73 m² per 24 hours, and there was microscopic haematuria.

The ideal treatment for hepatitis B associated membranous nephropathy in children is yet to be determined. There is one retrospective analysis of six studies comprising a total of 82 children that showed 60% complete remission 12 months after the diagnosis, 7.3% renal failure, 2.4% end stage renal failure, and 30% persistent disease. Steroid therapy should not be used as it does not appear to be beneficial, and the steroids may enhance viral replication in mononuclear cells. The average duration of proteinuria is 30 months. We believe that treatment with lamivudine in this case likely suppressed the virus and resulted in early remission of clinical nephrotic syndrome; however, the subsequent rebound in viral load and renal biopsy results probably indicates loss of viral suppression, leading to the subclinical relapse. It is unknown at this time if the strain of hepatitis B has developed resistance to lamivudine. Effective viridal agents may be needed to prevent relapses of hepatitis B induced membranous nephropathy. Finally, further work is needed to investigate the efficacy of this treatment in a larger cohort and to establish guidelines about the duration of such therapy.

PCD or not PCD

In response to the leading article on primary ciliary dyskinesia (PCD) and the commentary by Dr Andrew Boon, we write as clinicians with an interest in PCD who work in general paediatrics and neonatology. We agree with Dr Boon that the identification of an uncommon medical disorder from the large number of children presenting with common symptoms and signs is a major challenge for the general paediatrician. We also support the view that it is undesirable and certainly impractical to refer every child with recurrent episodes of cough, rhinitis, and chronic otitis media for further investigation. However, we believe that the aim of the editorial by Professor C O’Callaghan and Dr A Bush was to provide information on subtle differences in the clinical presentation of PCD to help us differentiate these patients from those with common non-specific childhood respiratory problems. For example, it is uncommon for a term infant to be admitted to a neonatal unit with significant respiratory concerns following a vaginal delivery but common in infants with PCD. We performed an as yet unpublished questionnaire survey of individuals belonging to the PCD support group which identified that 47% had been admitted to a neonatal unit with unexplained respiratory problems following a normal vaginal delivery. Rhinitis is also very rarely seen in normal neonates but is extremely common in patients with PCD. Other subtle clues increasing the likelihood of PCD are the characteristic of the cough and middle ear problems especially the development of persistent otitis media after tympanostomy tube insertion.

There is of course no doubt that a cheap reliable screening test would significantly help promote early diagnosis of PCD but it is not yet on the horizon. A detailed history especially of the neonatal period will help those working in neonatology or general pediatrics to highlight the patient that should be referred for further investigations including cilia studies.

Hazards in the epidemiological study of sudden infant death syndrome

The study of Platt and Pharaoh, confirms the increased risk of SIDS in twins compared with singletons. They point out that a major component of that higher accrued risk is that twins tend to be of low birthweight. Their finding that like-sex twins are at no greater risk than unlike-sex twins adds to the substantial evidence concerning the very limited role of genetic susceptibility for SIDS, and the rarity of recurrence in siblings of victims.

The authors illustrate the gratifying fall in the number of SIDS during the six years of their 1990s study. As the number of infants categorised each year as SIDS in England and Wales comes nearer to that of 200, so it becomes more important for those involved in epidemiological studies to be sure that the categorisation (i.e. the diagnosis) is correct. I refer to infants who, a few years after they have been categorised as SIDS, have been re-assessed, usually because of a subsequent child being abused or killed, and, in the course of court proceedings, findings are made that
the previous infant(s) were killed by the par-
ent, rather than dying of natural causes. Cur-
rently, there does not seem to be a mechanism for correcting the national childhood mor-
tality statistics when later, correct diagnoses are made. For instance, in the 1990s, I am aware that at least 20 infants who were initially categorised as SIDS, but who in later years, after extensive child protection investigations, were deemed to have been killed, usually by smothering. Colleagues will know of other cases: the true number will be higher. It is unfortu-
ate that the official statistics do not seem to be altered retrospectively, and remain a misleading figure for any research worker. I should add that, since none of the cases of parental killing of which I am aware involves twins, the conclusions of Platt and Pharoah are more likely to have been strengthened rather than weakened by such false diagnosis. However, the number of SIDS continues to fall, it will become ever more difficult for re-
search workers to compare small sub-
groups of SIDS within national mortality sta-
tistics unless the statistics are revised retro-
spectively in response to later correct diag-
nosis.

It is appropriate to warn of an additional hazard for research workers in this field. In the same issue of Archives there was an inter-
view with a group of epidemiologists in New York concerning the possibility of vagal over-
activity as a cause of sudden infant death.7 They referred to a “positive family history of SIDS”. A particular hazard there is that, unless details of that family history are veri-
fi ed in considerable detail, mistakes may be made. In recent years I have been involved with families in which parents who have recently lost a child have been provided to paediatricians, genetic counsel-
ing services, and to SIDS research workers, a false family history of SIDS—for instance, mother saying that two of her own siblings “died of SIDS”. Such statements invariably are taken at face value and become part of the medical history: they are included in family trees in the hospital notes, and they have been quoted and displayed in published research concerning SIDS, yet subsequent questioning of the relevant grandparent has revealed that no such infant deaths occurred. Presumably, the mother responsible for smothering or kill-
ing her child has invented the family history; either to gain more medical attention for her-
self, or as a cover to distract from her actions. A second reason for verifying the alleged pre-
vious infant deaths in more detail is that, even if a death has occurred, it is necessary to ex-
tend the extent of the contemporary inves-
tigation and pathological examination. In one of Professor Emery’s studies of infants ini-
tially categorised as SIDS, detailed re-
assessment pointed to either a definite natural cause, or abuse, in two thirds of case-
s.8

Use of inhaled corticosteroids in children

I read with interest the article Survey of adre-
nal crisis associated with inhaled cortico-
steroids in the presence of increasing doses of FP and the accompanying editorial in the Decem-
ber issue of Archives.

In the reported cases, the children had been 
administered substantially (up to 5 times) higher than the Glaxo SmithKline (GSK) Core Data Sheet recommended Flixotide dose of 400 mcg/day and use of fluticasone (FP) at such doses is certainly not endorsed by GSK. Within the recommended doses, there are a wealth of data from controlled clinical trials that Flixotide is a well tolerated and effective drug in adults and children.4,9 There are a number of recent studies in children which identified no cases of adrenal crisis and no effect on growth following 12 months treat-
ment with FP at licensed doses.10

There are also a number of methodological deficiencies in this survey, the most important being that the survey is not case-controlled and lacks information on true incidence and the overall FP use or exposure. In addition, it is unclear from the survey what attempts were made to closely monitor any adrenal suppression at increasing doses of FP or whether patients were down-titrated to the lowest effective FP dose, as routinely recommended.

The survey data also imply that fluticasone has been implicated in the great majority of cases of adrenal failure even though it is the least frequently prescribed form of inhaled corticosteroid. Prescribing data in relation to Flixotide and equivalent brands from the DINLINK (Doctor's Independent Network) database, shows that it is in fact the most commonly prescribed inhaled corticosteroid in children with mod-
erate and severe asthma.11 DINLINK is an amal-gamated database of the anonymised computer records of a panel of 300 general practitioners spread across the UK selected to repre-
sent the demographic population of the UK.

In addition, the authors’ contention that adrenal effects with FP are due to its greater lipophilic component accumulation in prolonged periods is misconceived and inac-
curate. There are studies to show that there is accumulation of FP at a steady state.12 It is the clearance value which determines the amount of FP in the body at steady state, and lipophilicity per se in not a relevant factor.2

I also wanted to take this opportunity to comment on the editorial by Dr Russell. The last line of the editorial recommends that if high dose inhaled corticosteroids is considered necessary, then it is advisable not to use fluti-
casone. The recent publication by the CSM “Current Problems in Pharmacovigilance” states that adrenal suppression is a dose related class effect of inhaled steroids, and that all inhaled corticosteroids are associated with an increased risk of adrenal crisis when used at higher than licensed doses.

In conclusion, inhaled corticosteroids have an important place in asthma management throughout the world, and this paper by Todd et al should be reviewed in this context. Any inhaled corticosteroid used at such high 
doses has the potential to cause systemic effects, and paediatricians should be encouraged to treat their patients using the lowest effective dose, down-titrating as appropriate.
