Chloramphenicol or ceftriaxone, or both, as treatment for meningitis in developing countries?

T Duke, A Michael, D Mokela, T Wal, J Reeder

Aims: To determine in children with meningitis whether there is any difference in mortality and neurological sequelae using chloramphenicol as first line treatment, with a change to ceftriaxone if chloramphenicol resistance is shown in vitro, compared to using ceftriaxone as first line treatment, with a change to chloramphenicol if there is no evidence of in vitro resistance.

Methods: An observational study with a retrospective control group nested within a randomised trial of fluid management for bacterial meningitis where clinical care was standardised. Chloramphenicol is standard treatment for bacterial meningitis in Papua New Guinea. In the first 150 cases we used chloramphenicol and only changed treatment to ceftriaxone if chloramphenicol resistance for cerebrospinal fluid isolates was proved. After finding 20% of Haemophilus influenzae were resistant to chloramphenicol, and that most affected children had poor outcomes, we changed to an alternative strategy. In the next 196 cases first line treatment was ceftriaxone and treatment was changed to chloramphenicol if the isolated bacteria were found to be susceptible.

Results: When chloramphenicol was used as first line treatment for meningitis followed by ceftriaxone when in vitro resistance was shown, there was invariably a very poor outcome in chloramphenicol resistant disease (71% of children died or had severe neurological complications). Using ceftriaxone as first line treatment was effective in reducing mortality and neurological sequelae from chloramphenicol resistant Haemophilus influenzae type (71% vs 9%, relative risk 0.13; 95% CI 0.02 to 0.87; p = 0.013). Changing to chloramphenicol if there was no evidence of in vitro resistance was less than half the cost of empirical use of ceftriaxone for a full course for all children with meningitis.

Conclusions: Using a third generation cephalosporin as first line treatment is effective in dealing with the problem of poor outcomes from meningitis due to Haemophilus influenzae that is resistant to chloramphenicol, and a strategy of changing to chloramphenicol if in vitro susceptibility is shown will reduce the use of expensive third generation cephalosporins without compromising on clinical outcomes. This highlights the urgent need to reduce the costs of third generation cephalosporins, to improve bacteriological services in developing countries, and to introduce effective and affordable vaccines against Haemophilus influenzae and Streptococcus pneumoniae.

METHODS

Antibiotic protocols

From August 1997 to October 2000 a controlled trial of fluid management in meningitis was performed in three hospitals in Papua New Guinea.20 Between August 1997 and September 1999, for the first 150 cases enrolled in the trial, chloramphenicol (25 mg/kg every six hours) was used as first line antibiotic treatment. As third generation cephalosporins were in very limited supply we changed to ceftriaxone only if resistance was found on cultured CSF isolate. This inevitably

Data analysis

Data were entered into an Excel spreadsheet and analysed with Stata 7.0 (Stata Corporation, Texas). We have analysed the outcome data according to whether chloramphenicol or ceftriaxone was used as first line treatment, for all cases of meningitis, those due to Haemophilus influenzae, and those due to chloramphenicol resistant bacteria. Outcomes were analysed using Fisher’s exact test and presented as relative risk and 95% confidence intervals (95% CI). We estimated the power of our analysis using Stata 7.0 (sampsi command). For comparison of baseline characteristics of the two groups, Student’s t test was used for comparison of means of continuous variables with normal distribution; the Mann-Whitney U test to compare variables with marked skewness of distribution, and the χ² test or Fisher’s exact test for comparison of proportions.
RESULTS
A total of 346 children were enrolled; 150 treated initially with chloramphenicol and 196 treated initially with ceftriaxone. Table 1 outlines the baseline clinical and laboratory characteristics of the children. Twenty one per cent of culture positive Hib isolates were chloramphenicol resistant; this translated to just 5.8% of all laboratory confirmed cases of meningitis. There was only one child in each treatment group who had a chloramphenicol resistant S pneumoniae, and both had good outcomes after treatment with ceftriaxone. In the first 150 cases we changed to ceftriaxone in eight (seven Hib and one pneumococcus), and in the next 196 cases we continued ceftriaxone for a full course in 12 (11 Hib and one pneumococcus).

Table 2 outlines the outcomes for children treated with the two antibiotic strategies. With the change from first line treatment with chloramphenicol to ceftriaxone, there was a 16% reduction (32% v 27%) in severe adverse outcomes for all meningitis (relative risk 0.67: 95% CI 0.44 to 1.00). This difference was not statistically significant (Fisher’s exact test, \( p = 0.34 \)); however, the estimated power of the analysis (to find an absolute difference of 5% from the baseline adverse outcome of 32%) was low: 0.14. There was a 31% reduction (relative risk 0.69: 95% CI 0.44 to 1.00, \( p = 0.35 \)) in severe adverse outcome in cases of culture or antigen positive Hib meningitis. In the subgroup of children with chloramphenicol resistant Hib isolates, there was a significantly better outcome in those treated empirically with ceftriaxone (relative risk of an adverse outcome 0.13; 95% CI 0.02 to 0.87; Fisher’s exact test, \( p = 0.013 \)).

On average the cost per patient of the second antibiotic strategy was two and a half times greater than using chloramphenicol as the only treatment, but less than half the estimated cost of using ceftriaxone for a full course for all cases.

DISCUSSION
Using ceftriaxone as first line treatment and changing to chloramphenicol in cases of in vitro susceptibility was effective in reducing adverse outcomes from bacterial meningitis, compared to using chloramphenicol as first line treatment and later change to ceftriaxone if the bacteria isolated were proven to be resistant. This is not altogether surprising as delays in effective treatment of two or three days in bacterial meningitis may have serious consequences, although previous evidence for a detrimental effect of prehospital delay is not strong. The median duration of symptoms prior to presentation in the children in this study was just over six days, and we found longer duration of symptoms was associated with higher probability of adverse outcomes. 13

Our study was a retrospective before-and-after comparison, and there are several potential sources of bias that require scrutiny. If case management of meningitis had improved over the two and a half years when the study was conducted, this would bias the data in favour of ceftriaxone. This may have been a factor, however the supportive management protocols were fixed from the beginning of the study, so it is likely that such an effect was minimal. The risk factors for an adverse outcome in the 346 children overall were longer duration of symptoms, spasticity, sunken eyes or reduced skin turgor, malnutrition (weight <80% expected for age), and hypoglycaemia. 19 Children who were initially treated with chloramphenicol had a significantly longer duration of symptoms prior to presentation (7.0 v 5.6 days), and a higher proportion of them were cyanosed at presentation, which may be expected to have biased the results towards a higher adverse event rate for those children treated with chloramphenicol. On the other hand the ceftriaxone group had higher CSF white cell counts, a higher proportion of S pneumoniae, and fewer cases of aseptic meningitis, which may be associated with a lower rate of adverse outcomes. 20-21 These, and other potential biases could only be overcome by a randomised trial. We did not find an overall statistically significant difference in adverse outcomes for all children with meningitis using ceftriaxone compared with using chloramphenicol, although we have inadequate power for a definitive conclusion. To detect a 20% relative difference in mortality or severe sequelae (32% reduced to 25.6%), a sample size of 1630 patients would be required.

Of the 15 previous studies comparing chloramphenicol and third generation cephalosporins, one reported a higher incidence of mild to moderate motor sequelae with chloramphenicol at discharge but not at four months after diagnosis, 22 one a higher incidence of transient ataxia and prolonged fever in the ceftriaxone group, 2 two others more prolonged fever in the chloramphenicol groups, 23-two reported a faster rate of CSF sterilisation with ceftriaxone, and two studies reported cases of recurrence that occurred in patients on chloramphenicol 24 and ceftriaxone. 25 There were no differences found in long term or severe neurological sequelae or mortality, although the power of these studies was low. Our study found little difference in outcome of meningitis for children treated with ceftriaxone or chloramphenicol, as long as there was in vitro susceptibility to chloramphenicol. A beneficial effect of ceftriaxone over chloramphenicol will be dependent on the proportion of resistant cases within the meningitis population. The much lower rates of resistance in earlier studies and their small sample sizes will account for why so few of the earlier studies found a difference in major outcomes. The treatment strategy we used can only be applied to settings where antibiotic susceptibility testing can be done. Unfortunately in Papua New Guinea, like many developing countries, this is only possible at a few of the major hospitals. Lack of diagnostic facilities at first and second level referral hospitals is a problem in many developing countries, and has major implications for introduction of treatments considered “standard” in industrialised countries. The scant data from previous comparison trials also highlights a major deficit in understanding the extent of antibiotic resistance in less developed countries.

In most developing countries, to change standard treatment to empirical use of ceftriaxone for all cases of meningitis would be two edged sword. It would save the lives of many...
children but add substantially to the cost of meningitis treatment, and uncontrolled use of third generation cephalosporins may risk more rapid development of antibiotic resistance. In hospitals without bacteriology services antibiotic resistance may only manifest as an increasing proportion of clinical failure and unexplained deaths. The emergence of ceftriaxone resistance in developing countries, now a real problem in some industrialised countries, would be a disaster, and every effort should be made to prolong the effective lifespan of both chloramphenicol and ceftriaxone for serious illnesses by evidence based approaches to antibiotic prescribing. If standard treatment policies cannot be implemented because of non-availability or high costs of drugs, this can undermine confidence in the programme. However, to continue to use chloramphenicol as first line treatment in the setting of high resistance or to use ceftriaxone only in children who are not showing clinical improvement after 2–3 days (one possible strategy where bacteriology facilities are absent) will be associated with a very high case fatality or severe brain injury, as we experienced among the first 150 cases. These highlight the importance of lowering the cost of third generation cephalosporins and developing minimal bacteriological facilities in hospitals in developing countries to include CSF collection cephalosporins and developing minimal bacteriological facilities in hospitals in developing countries.

In settings where pneumococcal resistance to chloramphenicol is low, introduction of conjugate Hib vaccine would almost eliminate the need to use third generation cephalosporins for bacterial meningitis, and chloramphenicol could again be effective standard treatment. Unfortunately, in the past 18 months in Papua New Guinea, S pneumoniae meningitis that is resistant to chloramphenicol is emerging. Pneumococcal resistance has been present for years in many other developing countries, many of which are now also reporting high rates of Hib resistance and the emergence of ceftriaxone resistance. It is clear that affordable pneumococcal vaccine strategies and Hib vaccine are the only long term solutions to the excessive mortality and suffering caused by bacterial meningitis worldwide. Until then it is essential that third generation cephalosporins are made available and bacteriology services developed.

ACKNOWLEDGEMENTS

We thank Drs Joyce Mgone, Dale Frank, and Charlie Turhurrs for collecting data for the fluid management study, from where the data for this study were derived. We thank the nursing staff of the children’s wards of Goroka and Port Moresby General Hospitals for their care of the children involved. We thank David Fuller for supplying some of the data on previous comparison trials of third generation cephalosporins and chloramphenicol. TD thanks Alison Duke for her constant support.
