Atomoxetine: a new pharmacotherapeutic approach in the management of attention deficit/hyperactivity disorder

J Barton

Atomoxetine is a novel, non-stimulant, highly selective noradrenaline reuptake inhibitor that has been studied for use in the treatment of attention deficit/hyperactivity disorder (ADHD). Data from clinical trials show it to be well tolerated and effective in the treatment of ADHD in children, adolescents, and adults. Improvements were seen not only in core symptoms of ADHD, but also in broader social and family functioning and self-esteem. Once-daily dosing of atomoxetine has been shown to be effective in providing continuous symptom relief. Atomoxetine does not appear to have abuse potential and is associated with a benign side-effect profile. The development of atomoxetine thus represents an important advance in the pharmacological management of ADHD.

Pharmacotherapy is an important component of the multimodal management of attention deficit/hyperactivity disorder (ADHD), but currently this approach is restricted by the limited range of licensed drugs. Management to date has been dominated by the use of the psychostimulants methylphenidate and dexamphetamine, for which there is a substantial evidence base describing their efficacy. Although the range of formulations of psychostimulants has increased over the years to include long acting and continuous release formulations, their use is limited by their duration of action, problematic adverse effects, abuse potential, and reluctance on the part of some children and families to take controlled drugs. A range of other drugs including tricyclic antidepressants, venlafaxine, guanfacine, and clonidine are also used in the management of ADHD; however, the evidence base for their effectiveness is less extensive than that for the psychostimulants and none are licensed for this purpose.

The focus of treatment to date has been on the relief of the core symptoms of ADHD. However, there is an increasing awareness of the need to address not only the immediate control of symptoms, but also broader treatment goals encompassing the quality of life of the affected individual and their family. The nature of ADHD is such that effects can be pervasive, adversely affecting school, home, and social life. It is associated with adverse outcome in terms of poor peer and family relationships and academic underachievement. ADHD can persist through childhood and adolescence into adult life, with implications for affected individuals across their lifespan including a potential requirement for lifelong treatment. Because of the limitations of existing treatments and the paradigm shift in thinking about the management of ADHD, there is an interest in the development of new pharmacological treatments.

ATOMOXETINE HYDROCHLORIDE: A NOVEL TREATMENT FOR ADHD

Atomoxetine is the first non-stimulant to be approved for the treatment of ADHD and the first drug to be licensed for the treatment of ADHD in adults. Atomoxetine was licensed in the US in November 2002 and in the UK in May 2004. At the time of writing, it is under consideration for licensing by the regulatory authorities in a number of other countries.

Clinical pharmacology

The neurobiological evidence suggests that drugs that have an effect on dopamine and noradrenaline may have therapeutic potential in ADHD. Atomoxetine (chemical designation: benzene-propanamine; (+)-N-methyl-3-phenyl-(o-tolyloxy)-propylamine hydrochloride; molecular formula: C_{17}H_{21}NOHCl) (fig 1) affects the regulation of noradrenaline. It is a highly selective inhibitor of the presynaptic noradrenaline transporter with little or no affinity for other neurotransmitter transporters and receptors. It increases the availability of extracellular noradrenaline in the prefrontal cortex and also increases dopamine levels in this region, but not in the nucleus accumbens or the striatum. This mechanism of action suggests that atomoxetine is unlikely to have abuse potential or to cause motor tics.

Atomoxetine is rapidly absorbed after oral administration and can be taken with or without food. Peak plasma levels are reached 1–2 hours after ingestion. Atomoxetine is metabolised by the majority of the general population through the cytochrome P450 2D6 pathway, 5–10% metabolise it more slowly through a combination of cytochrome P450 and P2D6 enzymes. The half-life of atomoxetine is 5.2 hours in rapid metabolisers and 21.6 hours in slow metabolisers, but metaboliser status does not affect dose, dose schedule, or side-effect profile. Atomoxetine is mainly excreted in the urine (80%) with the remainder being passed in the faeces. Atomoxetine does not appear to induce or inhibit the cytochrome P450 2D6 enzyme system, but other medications that do (for example, paroxetine) increase the availability of atomoxetine.

In vivo studies indicate that atomoxetine administration with substrates of CYP2D6 and CYP3A does not result in clinically significant drug interaction.
with desipramine, a model compound for drugs metabolised by CYP2D6, did not alter the plasma pharmacokinetics of atomoxetine or desipramine. Similarly, co-administration of atomoxetine with midazolam, a model compound for CYP3A metabolised drugs, resulted in only a minor statistically insignificant increase in midazolam plasma exposure.22

The effects of atomoxetine seem to last longer than would be expected from its pharmacokinetics in that once-daily administration is effective, with behavioural control continuing after the drug has apparently been cleared from the plasma.13 The reasons for this are not clear, but may be explained by differences in brain and plasma pharmacokinetics or by continued effects on the noradrenaline transporter.

Clinical studies

The efficacy of atomoxetine in ADHD was first examined in adults in a double blind, placebo controlled study, the results of which demonstrated its superiority over placebo in reducing ADHD symptoms and that it was well tolerated.14 This was followed by an open label pilot study and a dose ranging study in children and young people, both of which were positive in demonstrating efficacy and tolerability.15 16

An extensive clinical trials programme has been designed to investigate the detail of atomoxetine’s therapeutic potential. As part of this programme, eight paediatric randomised, double blind, placebo controlled trials of efficacy have been published to date (table 1).

In all of the studies (adult and child) subjects had to meet Diagnostic and Statistical Manual of Mental Disorders (DSM) criteria for ADHD. Exclusion criteria included having comorbid diagnoses with major depression, marked anxiety, or history of bipolar depression or psychosis, major physical illness, alcohol abuse, active use of illicit drugs, or having an IQ of less than 75. In the adult studies,14 17 subjects must have a BMI of less than 30, not be on any other medications, and have a stable treatment plan. Subjects with DSM-III-R defined ADHD, similar reductions in ADHD symptoms were seen in both the atomoxetine and methylphenidate treatment groups. Safety and tolerability were also similar for the two drugs.

A six week, randomised, double blind, placebo controlled trial in children confirmed the observation that the duration of action of atomoxetine is longer than the five hour blood half life would otherwise indicate, and that once-daily dosing is effective in providing continuous symptom relief.13 The beneficial effects of atomoxetine were observed until the evening and settling at bedtime.13 In addition, a study by Kelsey et al20 showed that once-daily atomoxetine administration in the morning was associated with continuous symptom relief not only into the evening, but also into the following morning. Dose response in adults was found to be similar to that in children.21 A recent international study has confirmed the effectiveness of atomoxetine in non-North American children and young people.22

The clinical trials programme has examined in a preliminary way the broader efficacy of atomoxetine with secondary outcome measures addressing effects on comorbidities including anxiety, depression, and oppositional defiant disorder. Although studies have not been sufficiently powered to provide definitive evidence for efficacy they do indicate that atomoxetine may have beneficial effects in these areas.16 24 25 Broader social and family functioning has been assessed in two studies using the Child Health Questionnaire (CHQ), a parent rated health outcome scale that measures physical and psychosocial wellbeing. Michelson et al26 found that improvements in social and family functioning and self esteem were superior among atomoxetine treated patients compared with those in the placebo group. The 24 hour continuous symptom relief offered by atomoxetine, with the resulting treatment benefits during school time, family hours, and sleep may create a significantly greater potential for psychosocial improvements to child and family.

Although all of the studies were consistent in demonstrating the effectiveness of atomoxetine, a few limitations exist. In particular, there is a lack of data relating to the long term outcome of trials beyond nine weeks, although longer term data are emerging.27 In addition, limited information is available comparing atomoxetine to stimulants.10 28

Adverse effects and monitoring

In general, atomoxetine has been shown to be well tolerated. Wernicke and Kratochvil29 reviewed data from clinical trials and found that the most common drug related events reported were decreased appetite and an initial period of weight loss, followed by an apparently normal rate of weight gain. Serious adverse events have not been associated with the drug, and there have been few discontinuations due to adverse events. No evidence of insomnia has been found. Side effects encountered significantly more frequently than with placebo include dizziness and dyspepsia.22 In general, side effects have been noted to be transient, occurring primarily during the initiation and titration of atomoxetine.20

Particularly encouraging are the benign cardiovascular findings associated with atomoxetine treatment. For both adults and children, administration of atomoxetine produced no effects on cardiac conduction, repolarisation, or rhythm,
and only small changes in blood pressure and heart rate. The cardiovascular profile of atomoxetine, therefore, offers a distinct advantage over other noradrenergic agents, such as tricyclic antidepressants, with their associated cardiovascular burden.

A placebo controlled study designed to compare the effects of abrupt discontinuation following acute treatment with atomoxetine in children, adolescents, and adults established that discontinuation of atomoxetine therapy did not result in the development of an acute discontinuation syndrome and was well tolerated.

Because atomoxetine does not increase dopamine in the nucleus accumbens, a region associated with excitation and pleasurable behaviours, it is not expected to have abuse potential. This may make atomoxetine more acceptable. In addition, atomoxetine does not exacerbate tics and it is potentially beneficial in patients with comorbid affective disorders.

### ATOMOXETINE: CLINICAL INDICATIONS AND USES

On the basis of the evidence described above it would appear that atomoxetine is a viable alternative for the management of ADHD. In particular, its profile addresses the need to consider more than the immediate relief of symptoms and to take into account the quality of life of affected individuals and their families across their lifespan. Atomoxetine provides 24 hour a day symptom relief with once or twice daily dosing. As well as relieving core symptoms, treatment with atomoxetine is associated with significant improvement in the quality of life of the affected child and their family, and in child self esteem. An unexpected finding has been the effect of atomoxetine on sleep: children are reported to sleep better, improving their quality of life and that of their family.

Atomoxetine does not appear to have any abuse potential, and so offers opportunities for treatment where substance misuse is an issue and also allows treatment without concern for potential black market value.

ADHD can be a lifelong disorder and thus there is a need to consider the potential requirement for treatment across the lifespan. Atomoxetine has been shown to be effective in children, adolescents, and adults and therefore offers opportunities for continuity of treatment. It is licensed for children aged 6 years and above.

Height, weight, pulse, and blood pressure of children and young people receiving atomoxetine should be monitored on a regular basis. Contrary to recommendations for stimulants, patients administered atomoxetine should not have drug holidays because of the mechanism of action of the drug. The dose of atomoxetine is calculated on the basis of body weight with a recommended target dose of 1.2 mg/kg. It is possible to increase this to 1.8 mg/kg if clinically indicated, but there are no safety and tolerability data for doses above this in children and young people. Atomoxetine administration with substrates of CYP2D6 and CYP3A does not result in clinically significant drug interactions.\textsuperscript{12}

The development of atomoxetine represents an important advance in the pharmacological management of ADHD. In order to provide high quality individualised treatment to children, young people, and adults, clinicians require access to a range of drugs, thus allowing treatment to be matched to patient characteristics and preferences. There is therefore the need for further rigorously evaluated, licensed pharmacological interventions for the management of ADHD across the lifespan.
