Complex but balanced chromosomal rearrangements can give rise, through recombination during meiosis, to complex unbalanced rearrangements. Here, we report on the case of a 21 months old child associating a 8q21.13 duplication and 8p23.3 microdeletion. The proposita was referred to our lab for cytogenetic exploration of a hydrocephalus associated with facial dysmorphism. He had also psychomotor retardation and microcephaly. The patient R-banding karyotype revealed a partial trisomy 8q captured by the p telomere of the same chromosome, whereas the parents' karyotypes were normal. CGH-array technique characterized breakpoints and estimated its size to 61.8 Mb. Interestingly, an additional cryptic loss of 260 Kb in 8p23.3-pter was also identified by the same technique. These anomalies were confirmed by FISH technique.

The partial deletion of a chromosome arm in combination with partial duplication of the other was evocative of a recombinit chromosome deriving from a parental pericentric inversion. We suggest, therefore, that a parental pericentric prezygotic 8p23.3-q21.15 inversion resulted in the complex unbalanced rearrangement of chromosome 8 in our patient. The clinical picture including hydrocephalus, inguinal hernia, long-term fever and psychomotor retardation, was described in patients with pure 8q2pter duplication. However, the 8p23.3 microdeletion may contribute to the psychomotor retardation, microcephaly and some minor dysmorphic features. Here we emphasize the fact that the 8p microdeletion would be cytogenetically undetectable in the absence of CGH-array technique underlying the need of entire genome high-resolution analysis in patients with idiopathic mental retardation and/or birth defects even in abnormal conventional karyotype cases.

The deletion of the long arm of chromosome 18 causes a contiguous gene deletion syndrome with a highly variable phenotype, usually related to the extent of the deleted region. The most commonly reported clinical features include: mental disabilities, decreased growth, microcephaly and facial abnormalities.

We report on a case with partial monosomy 18q22 derived from a maternal reciprocal translocation t(8;18). The patient was 7 months old referred for genetic exploration of neurodevelopmental delay, craniofacial dysmorphism, post natal growth retardation, choanal atresia, club foot and congenital hip dislocation.

Chromosome analysis from peripheral blood showed a 46, XY, der (18). Array CGH was performed and revealed a partial monosomy 18q21.33q22.31 of 15.3Mb associated with partial trisomy 8q24.12q24.23 of 22.7Mb region. These results were confirmed by FISH using telomeric 18q probe.

Chroanal atresia and skeletal malformation are in agreement with the monosomy 18q. Interestingly, the deletion includes GALR1 gene in 18q23 which encodes galanine receptor. Galanine is a neuromodulator that stimulates growth hormone secretion. MBP, and adjacent genes, are implicated in myelination process and haploinsufficiency explains partially developmental delay. Otherwise, the haploinsufficiency of the 18q22.3-q23 gene region is suggested to be a critical region for the immunoglobuline A deficiency which is significantly associated to celiac disease. Our patient has not until now immunological disorders.

The association deletion 18q22- GH deficiency and decreased myelination is now well established. The real therapeutic impact of GH treatment is discussed.

Duplication of the SOX3 gene in a SRY negative 46, XX male

doi:10.1136/archdischild-2012-302724.0740

Case presentation An 11 old patient with hypoplasia of the right kidney and hypospadias was found to be SRY negative, 46, XX. His parents and younger sister were healthy. His intelligence was normal (IQ 92) and he had no other anomalies. The behavior, growth and development were all normal. His testes were >4ml and the penis was 5 cm. Ultrasound and MRI did not show internal female genitalia, while confirming right kidney hypoplasia (as did the DMSA scan).

ACTH test showed normal basal and stimulated 17OH-progesterone excluding a form of 46XX DSD due to 21-hydroxylase deficiency. 11-DOC and 11S were normal at both baseline and after ACTH stimulation, excluding 11-hydroxylase deficiency. Cortisol levels were in the mid normal range at baseline and responded to stimulation, excluding primary adrenal insufficiency. Androstenedione.

The hCG test found testosterone in the low normal range for male sex and age at baseline. It rised up to 146 ng/mL indicating the presence of functional Leydig cells targeted by hCG. The stimulated ratio TDHT was 5.6, not supporting 5 alpha-reductase deficiency.
