Background and aims
Cardiovascular compromise is associated with poor outcome in the preterm neonate, with gestational age and male sex as independent risk factors for hypotension, developmental injury and death. Recent work has highlighted the microvasculature as important in the development of cardiovascular compromise in the preterm. We aimed to further characterise microvascular changes that occur in the preterm newborn, identify potential windows for therapeutic intervention and explore the mechanisms underlying this dysfunction.

Methods
Preterm neonates were studied during circulatory transition. Microvascular blood flow was characterised over time by laser Doppler. We developed a guinea pig model for studying the mechanisms underlying regulation of blood flow (delivery at GA62/71) and also undertook studies in the preterm piglet.

Results
We observed significantly different patterns of microvascular tone regulation between male and female human (p = 0.01) and guinea pig (p = 0.01) neonates. Overproduction of vasodilators (carbon monoxide r = 0.495; p < 0.001; hydrogen sulphide r = 0.37, p = 0.0004), and decreased sympathetic nervous activity (r = 0.424, p = 0.025) was associated with increased microvascular flow. We were additionally able to characterise aspects of this physiology in the preterm piglet.

Conclusions
We propose a paradigm shift whereby inherent physiological differences between the preterm and term, and male and female, lead to inappropriate dilatation of the microvasculature, insufficient preload to the struggling myocardium and functional hypovolaemia, thus resulting in central hypotension and cardiovascular compromise. We now have evidence of many of the mechanisms underlying this dysregulation and propose future research be directed at interventional opportunities.

Background and aims
Studies have shown evidence for universal neonatal screening for critical congenital heart defects (CCHD) with pulse oximetry (PO). However, the feasibility of CCHD screening after homebirth is unknown. We assess the feasibility of PO screening in the Netherlands, where there is a high percentage of homebirths and early discharge after uncomplicated delivery in hospital. Preliminary results of the first 6 months are given.

Methods
Since October 2013 a feasibility study is performed in the Leiden region. Pre and post ductal SpO2 are measured ≥1h after birth in term low-risk infants using Nellcor PO. The measurement is repeated at day 2 or 3. Infants with positive screenings are assessed at the paediatric department and echocardiography is performed in case of persistent abnormal SpO2 readings.

Preliminary results
In the study period 1417 infants were born in the Leiden region. Parents of 1093 infants consented for screening and 96% of all infants with parental consent were screened. Inclusion rate increased over time. In 13 infants screening was positive, of which 4 were not recognised and not referred. In 9 positive referred screenings, we detected 1 persistent pulmonary hypertension, 1 muscular ventricular septum defect, 1 patent ductus, 3 infants received sepsis therapy and in
3 infants measurements were normal in hospital. No CCHD was detected and there were no false negative screenings. 

**Conclusion** This is the first pilot study assessing CCHD screening after homebirths and early discharge from hospital. We anticipate to present the final study results at the EAPS.

**Neonatal Infections**

**PO-0513** THE INFLUENCE OF IGM-ENRICHED IMMUNOGLOBULIN THERAPY ON NEONATAL MORTALITY AND HAEMATOLOGICAL VARIABLES IN NEWBORN INFANT WITH BLOOD CULTURE-PROVEN SEPSIS

1A Abbasoglu, 1A Ecevit, 1AU Tugcu, 2E Yapakci, 3MA Tekindal, 1A Tarcan, 2E Ecevit. 1Neonatology, Baskent University, Ankara, Turkey; 2Neonatology, Ankara Guney Hospital, Ankara, Turkey; 3Biostatistics, Baskent University, Ankara, Turkey; 4Pediatric Infectious Diseases, Baskent University, Ankara, Turkey

10.1136/archdischild-2014-307384.1157

**Background and aims** The aim of this study is to determine the effects of adjuvant immunoglobulin M-enriched IVIG therapy on mortality rate, haematological variables and length of hospital stay in newborn infant with blood culture-proven sepsis.

**Methods** Demographic and clinical features and outcome measures of 63 newborn infant with blood culture-proven sepsis were retrospectively documented from the medical records. The patients were divided into two groups according to their treatment history. The patients in Group 1 received antibiotic therapy only and the patients Group 2 received both antibiotic and adjuvant IgM-enriched IVIG.

**Results** The study revealed that mortality rates were 28.1% and 12.9% in Group 1 and Group 2, respectively. The mortality rate was lower in group 2, but the difference between the two groups was not statistically significant (p = 0.21) Coagulase negative Staphylococcus was the most common type of bacteria isolated from blood cultures in both groups. When compared changing of laboratory results in both groups, haemoglobin, leukocyte count and CRP levels were different between two groups during the first three days of antibiotic treatment.

**Conclusion** Our study revealed that if diagnosed at an early stage and treated aggressively with appropriate and effective antibiotics, adjuvant IgM-enriched IVIG treatment have no additional benefits in neonatal sepsis.

**PO-0514** ASSESSMENT OF RED CELL DISTRIBUTION WIDTH IN NEONATAL SEPSIS AS A PROGNOSTIC FACTOR

1A Abbasoglu, 1U Tugcu, 2D Anuk Ince, 3E Yapakci, 4A Ecevit, 5A Tarcan. 1Neonatology, Baskent University, Ankara, Turkey; 2Neonatology, Gaziosmanpasa University, Ankara, Turkey; 3Neonatology, Ankara Guney Hospital, Ankara, Turkey

10.1136/archdischild-2014-307384.1158

**Background and aims** Red cell distribution width (RDW) is a measure of the variability in the size of red blood cells. RDW has been shown to be associated with mortality in adult patients with severe sepsis. However, RDW changes in neonatal sepsis prognosis has not been studied. We evaluated the RDW values of neonatal sepsis from our retrospective data.

**Methods** Complete blood count results were analysed retrospectively from 63 infants diagnosed with culture positive sepsis in Baskent University Hospital Neonatal Intensive Care Unit. The RDW difference between 1st and 3rd days and the ratio of the difference and 1st day RDW (change of percentage) were calculated.

**Results** Gestational age, birth weight and Apgar scores at 1 and 5 min, resulting in mortality and improving infants showed no statistical difference (p > 0.05). The change of RDW between 1st and 3rd days was not significant (p = 0.74). Percentage change of RDW values with mortality rates did not differ (p = 0.44 vs p = 0.85).

**Conclusions** RDW could be elevated in conditions with ineffective eritropoesis or any disease with destruction with red blood cells. During sepsis, RDW could be found increased because of the effect of proinflammatory cytokines on red cell production. In neonatal sepsis, RDW change was not found associated with prognosis. Elevated and variable RDW levels could be explained because of different postmenstrual and gestational ages like preterm infants.

**PO-0515** IS WHAT WE DO RATIONAL? IS Lumbar puncture indicated in asymptomatic newborns < 72 hours age with high CRP values?

H Abdelrhim. Neonates, North Bristol NHS Trust, Bristol, UK

10.1136/archdischild-2014-307384.1159

**Background** Despite of the high rate of doing (lumbar puncture) LP in neonatal units, the yield is very low. The incidence of early onset (<72 h) neonatal bacterial meningitis (EONM) was estimated to be approximately 0.3 per 1000 live births. One of the national standard indications for LP in neonates is raised CRP.

**Aim of the study** Evaluate the utility of lumbar puncture done routinely for clinically normal babies with raised CRP.

**Methods** Retrospective review of the indications, course, laboratory and clinical outcome of all term babies who had LP done in our unit over the last 10 years.

**Results** 142 newborn babies (gestation between 36 weeks) had LP done during this period in the course of sepsis and meningitis evaluation. 43 infants were excluded from the study due to incomplete medical records, none of them had meningitis. LP was done in <72 h of age in 66 babies.

None of the clinically normal babies with raised CRP had meningitis. None of the babies who had LP done <72 h had meningitis. All meningitis cases were significantly symptomatic. From 9 babies labelled meningitis only 3 babies had microbiological diagnosis of meningitis.

**Conclusion** Routine lumbar puncture for babies < 72 h of age may not be required in clinically normal term newborns with raised CRP. In babies with clinical sepsis, though the yield is not very high; there are no reliable clinical or laboratory markers to predict which babies will have meningitis and hence these babies would warrant a lumbar puncture.
